some are calcium-channel blockers, such as nifedipine; some are angiotensin converting-enzyme inhibitors, such as captopril and enalapril. Furthermore, their sites of action differ. Some have a predominant arterial vasodilator effect such as hydralazine,[2,3] minoxidil[4] and nifedipine[5,6]; some have a predominant venodilator effect, such as nitroglycerin[7,10] and isosorbide dinitrate[11,12]; and some have a balanced venous and arterial effect such, as sodium nitroprusside,[8,13–16] prazosin,[15,16] trimazosin,[17,18] captopril[19–21] and enalapril.[22] Despite these differences, all have been shown to favorably alter the hemodynamic pattern in patients with heart failure. Unfortunately, this short-term hemodynamic response is not a reliable guide to favorable long-term clinical response. The numerous early reports of long-term efficacy must be qualified because the observations were made in open-label trials. Furthermore, several more recent reports indicate that tolerance to these drugs, expecially prazosin[23,24] and hydralazine,[25] does develop.

Can we answer the questions of whether vasodilators are effective long-term therapy and, if so, are some more effective than others? Definitive long-term trials of these drugs are few. Furthermore, studies comparing relative efficacy of one vasodilator with another are only now being undertaken. However, a number of double-blind, placebo-controlled trials have been performed with the most frequently used vasodilators. These studies were similar enough in design to permit comparison. The drugs investigated were captopril,[26] enalapril,[27] isosorbide dinitrate,[28,29] hydralazine[30] and prazosin.[31,32] The patients included were all functionally limited but stable at the time of study. In each of the studies the patients were receiving optional conventional therapy with digitalis and diuretic drugs. Patients were randomized to either active drug or placebo and then monitored for 2 to 6 months with serial clinical evaluations and exercise-tolerance testing. The results of these trials are listed in Table I. Both captopril and

TABLE I Results of Double-Blind Placebo-Controlled Trials Using Vasodilators to Treat Heart Failure

Agent	Mechanism	Clinical Status	Exercise Capacity
Captopril[26] (300 mg/day)	Angiotensin converting enzyme inhibitor	Improved	Increased
Enalapril[27] (5 to 20 mg/day)	Angiotensin converting enzyme inhibitor	Impoved	Increased
Isosorbide[28,29] Dinitrate (160 mg/day)	Direct vasodilator	Improved	Increased
Prazosin[31] (16 mg/day)	α_1 blocker	Improved	Increased
Prazosin[32] (20 mg/day)	α_1 blocker	No change	No change
Hydralazine[30] (200 mg/day)	Direct vasodilator	No change	No change

isosorbide dinitrate improved patients symptomatically and functionally when compared with placebo. On the other hand, neither hydralazine nor prazosin was consistently more effective than placebo in treating patients with heart failure.

It is not clear why captopril and isosorbide dinitrate were effective and hydralazine and prazosin were not. This may be due to a higher incidence of tolerance with long-term hydralazine or prazosin administration even though individual patients did improve. It has been suggested that these drugs stimulate vasoconstrictor mechanisms (sympathetic nervous system or renin-angiotensin system) that override their acute vasodilator activity.[33,34] In the case of isosorbide dinitrate Leier et al[29] demonstrated that long-term efficacy was due to the persistance of venodilator and pulmonary vascular effects even though tolerance developed to systemic arterial dilation. As for captopril and enalapril, their long-term efficacy is probably dependent on a number of physiologic actions. Not only do they block the production of angiotensin II, but they also reduce peripheral sympathetic tone[35,36] and may inhibit degradation of the body's own vasodilator substances, bradykinins,[37] while stimulating prostaglandin production.[38]

These vasodilators redistribute blood flow to regional beds differently. Isosorbide dinitrate increases forearm blood flow but does not change renal or hepatic blood flow.[10,39] Prazosin increases hepatic blood flow.[40] Hydralazine increases both hepatic and renal blood flow to the same order of magnitude as global increases in cardiac output.[39] Finally, captopril and enalapril cause a relative reduction in hepatic blood flow while increasing both renal and cerebral blood flow.[22,41,42] These different patterns of redistribution of regional blood flow may participate in the symptomatic and functional improvement in patients on long-term vasodilators. Further studies are required to confirm this potentially beneficial mechanism and differentiate one vasodilator from another.

Deciding when to initiate therapy with a vasodilator is debatable. Many patients with early CHF will respond adequately to diuretics and digitalis alone. However, even here, the improvement is limited. Exercise testing often reveals significant functional limitation in the otherwise asymptomatic patient.

Certainly patients who remain symptomatic despite aggressive therapy with diuretics and digitalis should be considered for vasodilator therapy. Given the wide range of vasodilators to choose from, selection of a drug for long-term therapy can be tailored to the individual needs and tolerances of the patient. Good data exist for the efficacy of converting enzyme inhibitors such as captopril and enalapril as long-term vasodilator monotherapy. Isosorbide dinitrate also appears to be effective as long-term monotherapy. As a general rule, neither hydralazine nor prazosin seems to be effective, although individual patients may have a good long-term response. The potential benefits of combining different agents working on different vascular beds with different mechanisms of action may be attractive. Hydralazine and nitrates are often used in combination to achieve a balanced reduction of preload and afterload.[43,44] A recent report from Massie et al[45] demonstrated a further improvement in acute hemodynamic response by adding hydralazine to the drug regimen of patients already receiving captopril. This may well be the appropriate solution for the problem of tolerance that is seen with long-term therapy.

We do not know whether the use of vasodilators prolongs the life of a patient with CHF. Symptomatic heart failure carries a poor prognosis, with a 2-year life expectancy of about 50%.[46] By altering the working environment of the heart, vasodilators improve left ventricular function and might delay progression of the disease. The fact that to date no vasodilator has been shown to alter the natural history of CHF may be due to the type of patients studied. As a rule these studies have been performed in patients so severely compromised that they may not have the capacity to reverse a disease process so far advanced. Whether the use of vasodilators in the earlier phases of the disease could alter the natural course of CHF is not known. This rather somber note, however, does not obfuscate the fact that the addition of vasodilator drugs to the standard therapy of digitalis and diuretics may significantly improve the quality of life of patients with CHF.

Clinical and Hemodynamic Experience with Enalapril in Congestive Heart Failure

ROBERT J. CODY, MD

The renin-angiotension system is activated in many patients with congestive heart failure (CHF), resulting in angiotensin-mediated vasoconstriction and aldosterone-mediated sodium and water retention. To evaluate the effectiveness of enalapril, a new converting enzyme inhibitor, enalapril was administered to patients either orally or intravenously in a single dose, and hemodynamic and hormonal responses were measured. Patients were then placed on oral enalapril therapy for 1 month, and treadmill exercise duration and invasive hemodynamics were compared with baseline pretreatment data. With single-dose administration, both oral and intravenous enalapril reduced systemic vascular resistance and increased cardiac output. However, the effects of oral enalapril were not manifest for 3 to 4 hours, because oral enalapril is a pro-drug form that requires hepatic deesterification. In contrast, intravenous enalapril resulted in significant hemodynamic and hormonal changes 15 to 30 minutes after administration. During long-term therapy, enalapril was associated with improved symptomatology, increase of treadmill exercise duration and sustained hemodynamic improvement. Enalapril was effective therapy for chronic CHF. Optimal short-term response may require coadministration of both intravenous and oral preparations of enalapril; however, the magnitude of the short-term response was comparable for both preparations. Long-term therapy is most effective when the drug is administered as a twice-daily regimen.

(Am J Cardiol 1985;55:36A–40A)

Activation of the renin-angiotensin system in chronic congestive heart failure (CHF) is associated with an adverse hemodynamic profile caused by angiotensin-mediated vasoconstriction and aldosterone-mediated sodium retention.[1,2] Numerous factors may cause the release of renin in CHF[3] and renin is the rate-limiting enzyme for the generation of angiotensin II and aldosterone. Pharmacologic inhibition of the renin-angiotension system activity can occur at several points along the hormonal pathway (Fig. 1). However, the most practical and efficacious blockade of the renin-angiotensin system is by converting enzyme inhibition. This report outlines clinical and hemodynamic observations with enalapril, a long-acting converting enzyme inhibitor, in patients with severe CHF.

From the Department of Medicine, Cardiology Division, The New York Hospital–Cornell University Medical College, New York, New York. This study was supported in part by a General Clinical Research Center Grant (RR-047) from the National Institutes of Health, Bethesda, Maryland.

Methods

Eighteen patients with severe chronic CHF were enrolled in this study after providing informed consent for the described procedures. There were 15 men and 3 women aged 41 to 76 years. The cause of CHF was associated with ischemic heart disease in 11 patients and was idiopathic in origin in 8. No patient had valvular heart disease, and all were normotensive, without a history of sustained systemic hypertension. According to the New York Heart Association classification, 4 patients were functional class III and 14 were functional class IV. All patients had been receiving digoxin and diuretic therapy until the time of enrollment in this study, but these agents were withheld on the morning of study. Most patients failed to demonstrate clinical or hemodynamic improvement with other vasodilator drugs, and no vasodilator drugs were administered for at least 3 days before the study began.

Nine patients received oral enalapril (MK-421) as part of a dose-ranging study previously described,[4] and 9 patients underwent short-term dose ranging with intravenous enalapril (enalaprilat, MK-422). After the initial hemodynamic studies were completed, all patients received oral enalapril ranging in dosage from 2.5 to 10 mg administered twice daily. After 1 month of oral therapy, patients were admitted for a repeat hemodynamic study. All hemodynamic studies were per-

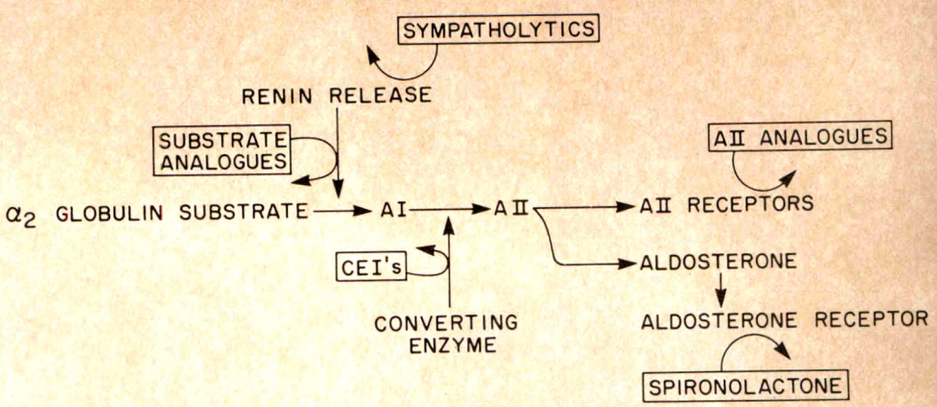

FIGURE 1. Renin-angiotensin cascade and locations for pharmacologic interruption (**enclosed rectangles**). From a clinical and practical point of view, only converting enzyme inhibitors (CEI's) are relevant for therapeutic interventions in congestive heart failure. Figure adapted from Cody and Laragh.[3]

formed the morning after overnight fast, as previously described.[5] Cardiac pressures and cardiac output were measured using a thermodilution right-heart catheter and systemic arterial pressure was determined from an indwelling arterial catheter. The heart rate was determined by continuous monitoring of precordial lead. All patients exercised on a treadmill using a modified Naughton protocol at the time of the baseline and 1-month admission.

Only 14 of the original 18 patients were studied after 1 month of treatment. One patient was lost to follow-up, 1 patient had a sudden cardiac death, 1 patient did not respond to enalapril and was placed on alternate drug therapy and 1 patient had acute renal failure in the setting of enalapril.

Assays of plasma activity and plasma aldosterone were performed using previously described radioimmunoassay techniques.[6,7]

Analysis of variance was used to assess the magnitude of hemodynamic change after the short-term administration of enalapril. To compare the baseline with the 1-month response, a paired t test was used, with each patient serving as his own control. Results were considered statistically significant if they achieved a p value ≤ 0.05.

Results

Table I is a list of the short-term hemodynamic responses to oral enalapril. The baseline hemodynamic values indicate severe CHF: the mean cardiac index was 1.56 liters/min/m^2, mean systemic vascular resistance was 1,687 dyne·s·cm^{-5} and mean pulmonary wedge pressure was 21 mm Hg. After oral enalapril treatment, no significant hemodynamic change was observed for the first 2 hours, with only borderline changes occurring by 3 hours. At 4 hours, however, significant hemodynamic effect was observed, as judged by an increase of cardiac index to 1.81 liters/min/m^2 and a reduction of mean arterial pressure to 67 mm Hg, reduction of pulmonary wedge pressure to 17 mm Hg and a reduction of calculated systemic vascular resistance to 1,378 dyne·s·cm^{-5}. The delay in onset of significant hemodynamic improvement is attributed to the fact that enalapril is administered in a pro-drug form. Enalapril must be metabolized by hepatic deesterification to the active drug, MK-422. This relatively delayed onset of converting enzyme inhibition was confirmed by the time required for appropriate hormonal response. Figure 2 shows the peak response of plasma renin activity and plasma aldosterone. Baseline renin activity was 9 ± 3 ng·ml^{-1}·hr^{-1}, and this increased to 35 ± 11 ng·ml^{-1}·hr^{-1} at 4 hours after oral adminstration of enalapril. Likewise, plasma aldosterone was 19 ± 4 ng/100 ml and this decreased to 9 ± 2 ng/100 ml (for both, $p < 0.02$). However, no significant changes in plasma renin or plasma aldosterone were observed at 1 and 2 hours after oral administration of enalapril.

Because oral enalapril must be metabolized to the active compound, it was difficult to immediately identify the magnitude of hemodynamic response that was likely to occur, as well as the degree of correlation of hemodynamic improvement with baseline renin-angiotensin system activity. For these reasons, we administered intravenous enalaprilat (MK-422), the active converting enzyme inhibitor. When given intravenously, the active compound results in a more dramatic and clear-cut hemodynamic response (Fig. 3). Much smaller doses of the active drug are required to achieve its hemodynamic effect. After an intravenous dose of 0.625 mg, there is prompt and marked reduction of systemic vascular resistance (from 1,998 to 1,497 dyne·s·cm^{-5}), and mean arterial pressure (from 85 to 72 mm Hg), associated with a reflex increase of stroke volume index

TABLE I Acute Response to Oral Enalapril (n = 9)

	Baseline	1 Hour	2 Hours	3 Hours	4 Hours
Heart rate (beats/min)	80 ± 5	81 ± 5	81 ± 6	80 ± 5	77 ± 5
Mean arterial pressure (mm Hg)	74 ± 3	75 ± 4	72 ± 5	68 ± 4*	67 ± 4*
Right atrial pressure (mm Hg)	11 ± 2	12 ± 2	10 ± 2	9 ± 2	9 ± 2

Cardiac index (liter/min/m^2)	1.56 ± 0.08	1.69 ± 0.09	1.73 ± 0.11	1.73 ± 0.13	1.81 ± 0.13*
Systemic vascular resistance (d·s/cm^5)	1,687 ± 128	1,552 ± 110	1,520 ± 165	1,459 ± 163	1,378 ± 172*

* $p \leq 0.05$

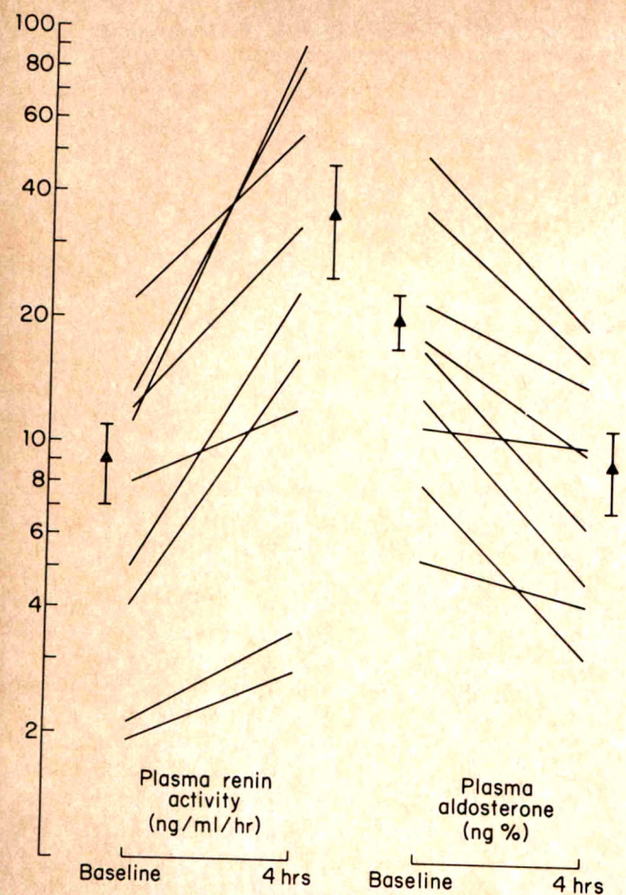

FIGURE 2. Short-term converting enzyme inhibition with oral enalapril resulted in significant increase of plasma renin activity and decrease of plasma aldosterone at 4 hours following oral administration of the drug. Both responses were significant ($p < 0.02$). Reproduced from Cody et al[4] with permission of the publisher.

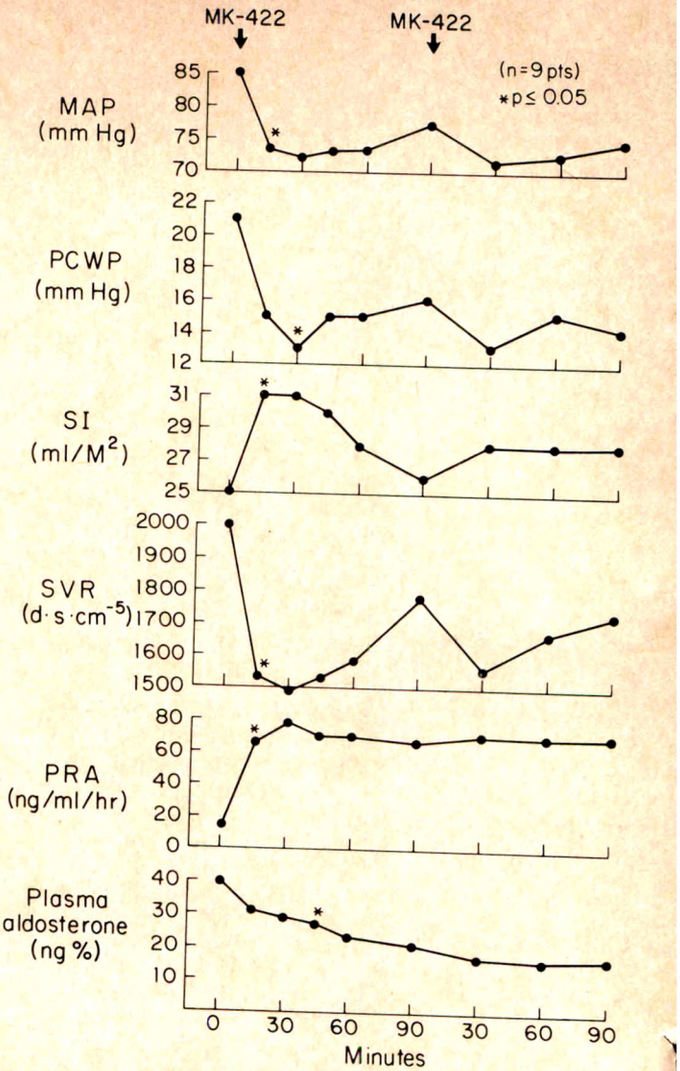

FIGURE 3. Mean hemodynamic and hormonal responses after intravenous administration of 2 doses of MK-422: the first dose was 0.625 mg; the second dose was 1.25 mg. MAP = mean arterial pressure; PCWP = pulmonary capillary wedge pressure; PRA = plasma renin activity; SI = stroke index; SVR = systemic vascular resistance.

(from 25 to 31 ml/m^2) and reduction of pulmonary wedge pressure (from 21 to 13 mm Hg). Within 15 minutes plasma renin activity had increased from 11 ± 4 to 64 ± 7 ng·ml^{-1}·hr^{-1} ($p < 0.001$). Plasma aldosterone changes were slower, owing to the relatively longer circulating half-life of aldosterone. At 90 minutes after administration of the first dose of enalaprilat, attenuation of the hemodynamic response occurred. However, with administration of the second dose, hemodynamic improvement was again observed, although the magnitude of increase of stroke volume index was much less.

To determine whether hemodynamic improvement would be sustained, we repeated the hemodynamic study after 1 month of oral enalapril therapy. We also compared the duration of treadmill exercise at 1 month to that measured at baseline, before drug administration. As shown in Table II, the increase in cardiac index and reduction in mean arterial pressure, pulmonary wedge and systemic vascular resistance were comparable to the observations made at the time of acute hemodynamic study. The plasma renin activity of 27 ± 6 ng·ml^{-1}·hr^{-1} was significantly increased compared with the baseline value of 12 ± 3 ng·ml^{-1}·hr^{-1}, providing evidence of sustained converting enzyme inhibition. This was confirmed by suppression of 24-hour urinary aldosterone excretion at one month. The duration of treadmill exercise nearly doubled from the baseline value of 310 ± 92 seconds to 572 ± 102 seconds.

Objective changes in hemodynamics and exercise duration were accompanied by subjective improvement. The New York Heart Association classification in the baseline state was functional class III for 3 patients and functional class IV for 11 patients. After 1 month of enalapril therapy, the same classification was functional class II for 5 patients, functional class III for 7 patients and functional class IV for 2 patients. In all but the last 2 patients, symptomatology had decreased by at least one functional class. While converting enzyme inhibition may be associated with orthostatic hypotension in the presence of diuretic therapy, this was not the case after one month of enalapril therapy. We were able to

obtain tilt hemodynamics before and after one month of enalapril therapy in 7 patients (Table III). Despite relatively low mean arterial pressure in the supine position, further significant reduction of mean arterial pressure during upright tilt did not occur.

Two adverse reactions were temporally associated with enalapril treatment. In 1 patient, transient acute renal failure occurred within 48 hours of intravenous enalaprilat and oral enalapril administration. This was evident by the presence of oliguria and increases in blood urea nitrogen and serum creatinine levels. When enalapril was discontinued, these values returned to normal levels. The patient declined a renal diagnostic workup to assess the status of his renal arteries. The second adverse reaction was a case of oral mucocutaneous ulceration and evanescent skin rash, which occurred during the fourth week of oral enalapril administration. The mucocutaneous changes resolved 3 to 5 days after discontinuation of enalapril, and the patient was not rechallenged.

Discussion

These data and those reported from others[8,9] indicate that enalapril is effective for long-term symptomatic and hemodynamic improvement in patients with severe CHF. Unlike direct vasodilators, however, the effectiveness of converting enzyme inhibitors depends on their ability to block angiotensin-mediated vasoconstriction. If the circulating levels of angiotension II or angiotensin occupancy of vascular receptors is minimal,[10] converting enzyme inhibitors are not expected to result in significant hemodynamic improvement. Indeed, one patient from our intravenous enalaprilat study had no hemodynamic improvement with enalaprilat and subsequent results from his hormonal profile confirmed suppressed renin-angiotensin activity.

The renin-angiotensin system is not uniformaly activated in CHF[1,2,11] and a number of factors can concurrently stimulate or suppress the extent of renal release. The net effect of these multiple interactions is a potential for fluctuating degrees of angiotensin-mediated vasoconstriction and aldosterone-mediated sodium retention. Some of the factors influencing renin-angiotensin inhibition are listed in Table IV. Probably the most important factor from the clinical point of view is the state of sodium balance, as sodium depletion is

TABLE II One-Month Response to Oral Enalapril (n = 14)

	Baseline		One month

associated with enhanced renin release.[12,13] In this setting, vascular tone is much more dependent on angiotension II, as compared to normal sodium intake. During sodium depletion, the hemodynamic response to converting enzyme inhibitors such as enalapril is likely to be associated with both supine and postural hypotension. Yet it is in this setting that converting enzyme inhibitors are much more effective for treating patients with CHF. On the other hand, sodium repletion, fluid overload or ineffective diuretic regimens are often associated with suppression of the renin-angiotensin system and endogenous angiotensin II activity;[14] in this setting, converting enzyme inhibitors are less effective. The long-term hemodynamic response to converting inhibitors is usually comparable to the short-term response because sodium depletion and diuretic therapy are generally held constant in heart failure patients. However, one can easily understand that a patient with acute fluid overload may have a poor initial response to enalapril yet respond on a long-term basis when diuretic therapy has been optimized. Conversely, an individual may exhibit a good response to enalapril while in the hospital, but deteriorate on an outpatient basis if dietary sodium is not carefully regulated. Thus, an individual patient's sodium status may be the most important long-term factor in response to converting enzyme inhibition.

In this study, enalapril was associated with simultaneous hemodynamic improvement marked by reversal of vasoconstriction and inhibition of the renin-angio-

TABLE III Effect of Long-Term Enalapril on Postural Hemodynamics

	Control		1 Month		
	Supine	Tilt	Supine		Tilt
Heart rate (beats/min)	81 ± 6	85 ± 5	77 ± 5		82 ± 5

TABLE IV Factors Influencing the Long-Term Response to Renin-Angiotensin Inhibition

Sodium intake/diuretic therapy
Alterations in renal blood flow and function
Interactions with other hormonal pathways
Progression or abatement of left ventricular dysfunction
Limitations/side-effects of drug therapy

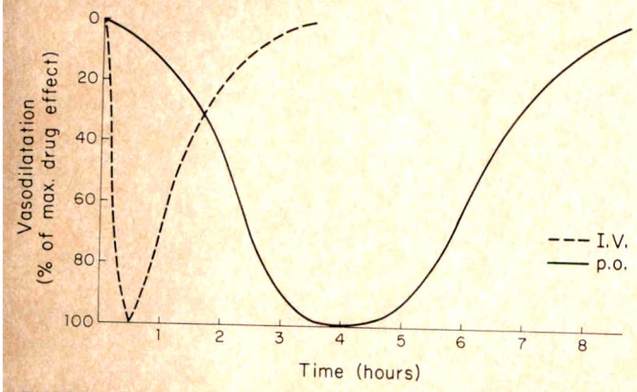

FIGURE 4. Relative time course of action of single dose of intravenous (I.V.) or oral (p.o.) enalapril. Vasodilatation, or reversal of vasoconstriction, expressed as percent of maximal drug effect over time is shown.

tensin system. There was a striking difference in the time course of the short-term response when the oral administration of the pro-drug MK-421, and the biologically active, deesterified active compound MK-422 were compared (Fig. 4). The first dose response must be interpreted in the context of the time course of action of the two different compounds. With intravenous enalaprilat or MK-422, the hemodynamic response to relatively small doses of the drug is prompt, and at times associated with marked reduction of blood pressure. In our experience, if there is no hemodynamic improvement within 60 to 90 minutes following a 2.5-mg dose of intravenous enalaprilat, it is unlikely that angiotensin-mediated vasoconstriction is occurring then, and the patient may require sodium depletion or alternate therapy. On the other hand, a marked response to intravenous enalaprilat suggests enhanced renin-angiotensin system activity and for clinical purposes, it may be necessary to decrease diuretic dosage temporarily. With oral administration of enalapril, the hemodynamic response may not be evident until 3 to 4 hours after its administration. In fact, for individual patients, it may be necessary to wait as long as 6 to 8 hours after drug administration to see a hemodynamic response.[8,9] Optimal oral therapy is 5 or 10 mg twice daily. At the initiation of therapy, it may be reasonable to administer intravenous and oral enalapril in close temporal succession, particularly if urgent intervention is necessary.

In terms of adverse reactions associated with enalapril, we observed one case of acute renal decompensation and one of mucocutaneous reaction.[15] While both adverse reactions were closely associated with the onset of enalapril administration, we cannot directly implicate enalapril in either case because neither patient was subsequently rechallenged with enalapril.

Enalapril has now been studied in more than 30 patients with chronic heart failure (Walker FJ: personal communication). These studies have demonstrated findings similar to those in our own laboratories, but in a broader range of patients. Significant improvement in hemodynamic status as well as exercise tolerance and New York Heart Association functional classification has been observed in patients who responded inadequately to digitalis/diuretic regimens. Patients have been treated with enalapril for periods longer than 2 years; chronic therapy has been well tolerated by most patients.

In summary, enalapril was associated with acute hemodynamic improvement when administered in either an intravenous or oral form. Long-term therapy was associated with improved symptoms and objective evidence of both exercise and hemodynamic improvement. It appears that enalapril is an effective converting enzyme inhibitor for the management of patients with chronic CHF.

New Positive Inotropic Drugs for the Treatment of Congestive Heart Failure

EDMUND H. SONNENBLICK, MD, DONNA M. MANCINI, MD, and THIERRY H. LeJEMTEL, MD

Positive inotropic agents can stimulate the severely depressed myocardium in late stages of heart failure. However, symptomatic benefits are only gained by improvement in the deranged peripheral circulation, which produces symptoms and limitations. In augmenting cardiac output and reducing filling pressures, the effects of positive inotropic agents and vasodilators are similar and additive, and the "contractile reserve of the heart" in response to inotropic stimulation may limit efficacy of these agents. Although symptomatic benefits occur in patients with severe heart failure after improvement in peripheral blood flow distribution, survival may not be altered, because this appears to be determined more by the amount of myocardial damage and its progression, and neither of these is affected by either inotropic agents or vasodilators. Indeed, in early stages of heart failure, therapy must be redirected toward preventing further myocardial cell loss rather than stimulating pump function.

(Am J Cardiol 1985;55:41A–44A)

Despite optimal current therapy with digitalis glycosides, potent diuretic drugs and vasodilator drugs, patients with severe chronic heart failure remain symptomatic and generally face a progressively declining clinical course with a rapidly fatal outcome.[1] Diuretic drugs are highly effective in control of sodium excretion, while various vasodilator drugs help to reduce the loads the heart must bear. Moreover, digitalis glycosides, which are the only oral inotropic agents clinically available to increase contractile force and, hence, improve depressed ventricular function, are limited in terms of their modest potency and associated toxicity. Thus, the search for new inotropic agents to stimulate the failing myocardium is a major pharmacologic challenge in the treatment of heart failure. At the same time, it is equally important to define the therapeutic target to determine the usefulness of such agents. Failure to do so may result in unfulfilled promises and unrealistic expectations.

The clinical entity of chronic heart failure has 2 components: *myocardial failure*, which leads to both acute and chronic pump dysfunction, and *congestive failure*, a more chronic derangement of the circulation with organ dysfunction resulting from excessive compensatory peripheral vasoconstriction and redistribution of peripheral blood flow. Myocardial failure can occur from a sustained overload with severe primary ventricular hypertrophy or from loss of myocardium, either segmental, as in coronary artery disease, or diffuse with focal loss of myocardium, fibrosis and resultant secondary hypertrophy, as in cardiomyopathies.[2,3] Hypertrophy of severe degree is then associated with depressed myocardial function, possibly because of abnormal calcium activation and decreased contractile protein function.[4] With substantial myocardial depression, ventricular dysfunction occurs; it is characterized by reduced systolic emptying despite increased diastolic volume, which translates clinically into a reduced ejection fraction and limited increase in cardiac output associated with effort.

The second component of chronic heart failure is congestive heart failure (CHF), which is the response of the circulation to pump dysfunction resulting from myocardial failure. Both the sympathetic nervous system and renin-angiotensin system are activated in CHF and contribute substantially to these vasoconstrictive changes.[5,6] Clinically, exertional fatigue results from a limited cardiac output, and shortness of breath and edema result from central and peripheral congestion. Sodium accumulation is also accompanied by profound alteration in peripheral blood flow distribution. Arterial vascular resistance is increased; in particular, it does not decrease normally during exercise so that blood flow to skeletal muscle is limited.[7,8] As will be discussed further,

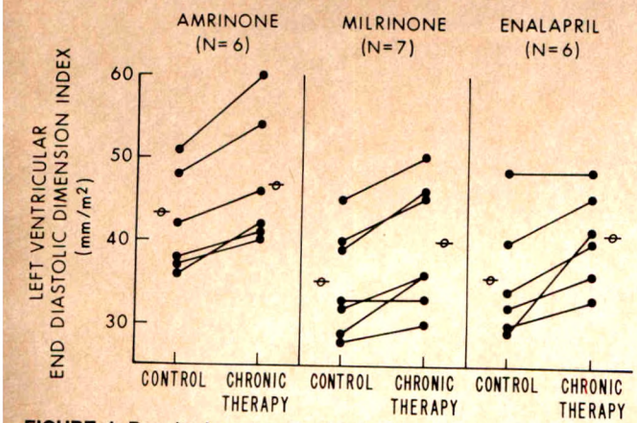

FIGURE 1. Despite long-term inotropic therapy with amrinone for a mean duration of 41 weeks (range 30 to 72) and milrinone for a mean duration of 50 weeks (range 30 to 79), or vasodilator therapy with an angiotensin converting enzyme inhibitor, enalapril, for a mean duration of 57 weeks (range 34 to 66), underlying myocardial disease progresses, as evidenced by increase in left ventricular end-diastolic dimension index (LeJemtel et al: unpublished observations).

limitation of function and changes in clinical status commonly reflect alterations in peripheral blood flow distribution rather than changes in ventricular contractility. Indeed, the ejection fraction, which reflects the extent of myocardial failure, correlates poorly with exercise performance,[9] although it correlates well with survival.[10] In acute heart failure, central fluid accumulation with limited cardiac output is a predominant feature and the peripheral derangements of CHF are generally absent.

The aim of treatment is essentially 2-fold: amelioration of symptoms and prolonged survival. These are not synonymous and need to be considered relative to the nature, severity and stage of disease. Most of the clinical trials in heart failure focused, quite naturally, on severe failure (class III and IV) with the aim of relieving symptoms. The effectivness of treatment was generally measured in terms of exercise performance. The assumption was that an increase in ventricular performance, characterized by an increase in cardiac output and a decrease in venticular filling pressure, would improve delivery of blood flow to exercising muscle and, hence, permit increased exercise performance. However, this has not been the widespread experience. Vasodilators such as captopril produce an immediate increase in caridac output, but exercise performance is not augmented until a few weeks have passed.[11] This reflects the fact that the immediate increments in cardiac output are distributed to the kidneys rather than exercising muscle.[12,13] Dobutamine, a potent inotropic agent, also augments cardiac output substantially while reducing filling pressure, but again blood flow to exercising muscle is not increased, so that exercise performance is not augmented immediately and arteriovenous oxygen difference actually narrows.[14]

In severe CHF, increased peripheral arterial resistance is not fully understood, but may reflect increased renin-angiotensin activity, increased α-receptor stimulation resulting from increased circulating norepinephrine or local mechanical changes in peripheral arterioles, perhaps secondary to sodium and water accumulation. Exercise performance is coupled to these limitations of skeletal muscle flow and as noted, either inotropic agents such as milrinone or vasodilators such as captopril, which exert similar and indeed additive hemodynamic effects,[15] do not increase exercise performance immediately. Thus, merely increasing ejection fraction and cardiac output may not improve symptoms because a substantial period is required before peripheral blood flow distribution improves, especially to exercising muscles. While changes in ventricular performance are very rapid in onset, changes in periphery circulation are not, so that either improvement or deterioration of the patient requires time and does not parallel the rapid improvement in cardiac function.[16] Some recently developed inotropic agents with direct arteriolar vasodilating properties, such as amrinone and milrinone,[17,18] can produce immediate dilatation of the skeletal muscle vasculature and rapidly increase submaximal exercise performance.[19]

The dismal survival rate of patients with severe heart failure is now well recognized[1] and has not been shown to be influenced by either vasodilator or inotropic therapy. This is not surprising if the pathologic characteristics of severe chronic heart failure are considered. Whereas ejection fraction, which reflects the extent of ventricular damage, does not correlate with exercise performance, it does predict survival.[9] Moreover, while chronic drug therapy may improve blood distribution and thus result in symptomatic improvement, the underlying cardiac disease appears to progress and ultimately leads to the death of the patient.[20]

Whether the inotropic agent itself contributes to further myocardial deterioration is not clear.[21] However, we have observed a progressive left venricular dilatation after long-term administration of both vasodilators and inotropic agents (Fig. 1). The fact that both types of agents produce the same end result despite fundamentally different modes of action suggest that "overstimulation" of the heart from the inotropic agent is not in itself producing further damage. It is of interest that the myocardial oxygen requirements of the heart actually decline when the depressed heart is reduced in size by inotropic agents. This decrease in oxygen use correlates with decreases in systolic wall stress, which far outweigh any increase in oxygen need that an augmented contractility might produce.[22] However, inotropic agents in general can induce ventricular arrhythmias and thus may contribute to the high incidence of sudden death in patients with severe heart failure. This possibility requires further study.

With these considerations in mind, the aims of treatment must be established in severe, as opposed to mild, heart failure. In severe failure, symptomatic relief is the primary endpoint, given the extensive cardiac damage that is generally present. "Cure" of the pathologic process is not possible, except with heart transplantation. Symptomatic relief is predicated on increasing the reduced cardiac output, although increments in skeletal muscle flow are necessary if exercise performance is to be enhanced.[23]

In contrast, the major therapeutic aim in the treat-

ment of patients with mild heart failure is preservation of myocardium rather than relief of symptoms.[24] Cardiac output is geneally normal at rest, and with exercise it increases substantially so that exercise performance may only be limited moderately, if at all. Prevention of sodium accumulation with diuretics may be all the treatment required. Inotropic stimulation of the heart to augment cardiac output may not be indicated because output is already normal. Indeed, such inotropic stimulation may actually be contraindicated, especially if calcium overloads may be a potential cause of small vessel disease and myocardial cell death.[25] The major aim at earlier stages of failure is to protect and preserve myocardial tissue and thus hopefully affect long-term prognosis. Whether early use of vasodilators to reduce loads and maintain smaller ventricular volumes will alter progression as well requires definitive study. Verapamil has been used in experimental cardiomyopathies[26] to stabilize cell membranes, inhibit small vessel spasm and prevent cell death; applicability of such experimental observations to man is not known.

In acute severe heart failure, acute pulmonary edema generally reflects acute abnormalities of ventricular function, yet chronic maldistribution of peripheral blood flow may not have occurred. Combined therapy with vasodilators, including morphine, potent, intravenously active cardiac stimulants such as dobutamine,[26] and diuretic drugs combine to produce immediate benefits when the underlying myocardial problem is reversible or limited.

In the normal as well as in the failing heart, cardiac muscle is only partially activated, and the extent of activation depends on the amount of calcium made available to the contractile system with each beat. The final common pathway of all inotropic agents appears to be the enhancement of calcium made available to activate the myocardial cell. Inotropic agents do not correct specific abnormalities in either the contractile apparatus or its activating system. The assumption with heart failure is that despite decreased overall ventricular function, the myocardium is still not fully activated, i.e.,there is a "contractile reserve" (Fig. 2). This may not be so in all cases and when myocardial failure is severe, little or no further ability to stimulate the myocardium may remain. Moreover, with drugs that are both inotropic agents and vasodilators, the primary action to improve cardiac performance, i.e., increasing cardiac output and decreasing ventricular filling pressure, may differ from case to case depending on whether significant myocardial contractile reserve is present.

Digitalis glycosides, which inhibit membrane Na+K+ ATPase to increase intracellular calcium, are modestly potent inotropic drugs. Their therapeutic use is limited by a lower toxic:therapeutic ratio. Catecholamines, which are depleted from the myocardium in severe failure, can still stimulate β_1 receptors in the failing heart. In severe failure, the density of β_1 receptors in the myocardium is reduced, which may make the heart less responsive to the inotropic effects of catecholamines.[27] Alternatively, the effective sympathetic nerve denervation seen in heart failure could enhance the availability of cathecholamines to the receptor sites (supersensitivity). The relative role of these opposing effects are unknown. Intravenous dopamine increases cardiac output and lowers filling pressure at rest, but these effects are lost during exercise, presumably owing to the increased endogenous circulating catecholamines that may saturate available myocardial receptors.[28] Dopamine is a less potent cardiotonic agent than dobutamine, but it specifically increases renal blood flow by stimulating dilatory dopaminergic receptors.[29] Levodopa, which is an orally active precursor, may be a useful adjunct in therapy if it is tolerated.[30]

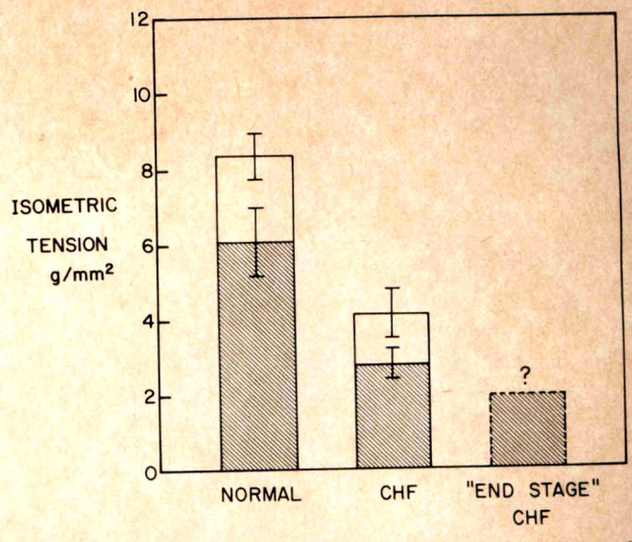

FIGURE 2. Effects of strophanthidin on maximal isometric force of contraction at length of muscle corresponding to apex of the active length-tension curve in 2 groups of muscles. Adapted from Spann et al, Circ Res 1967;21:348.

A new class of agents has been developed that are neither catecholamines nor digitalis glycosides. Amrinone was the first agent to undergo clinical trials. It produces phosphodiesterase inhibition and exerts both positive inotropic action and periphexal arterial dilatation.[31] Milrinone is an analog of amrinone and is 30 to 50 times more potent. Its hemodynamic benefits are similar to those produced by amrinone, but its long-term administration has not been complicated by the side effects observed with oral amrinone.[16,18] All of these agents have a similar effect on left ventricular performance, although the relative amounts of inotropic and dilating activity may differ. They were mostly studied in class III and IV patients, and shown to increase cardiac output and reduce ventricular filling pressures without significantly altering heart rate or blood pressure. Hemodynamic benefits were consistently observed and summate with those of vasodilators.[32] Combined vasodilator and inotropic therapy also provides for optimal blood flow distribution, such as increasing renal blood flow as well as reducing aldosterone secretion, as seen with captopril, and augmenting skeletal muscle blood flow and hence, exercise performance, as seen with milrinone.[15]

Although amrinone and milrinone both increase output and reduce filling pressure, the relative contributions of positive inotropic action and direct peripheral arterial vasodilation in producing these changes may vary from patient to patient. While routine hemodynamic measurements of cardiac output and ventricular filling pressures are affected similarly and in an additive manner by both actions, increments in the rate of left ventricular filling pressure development or increase in systolic emtyping of the ventricle for the same pressure are only produced by positive inotropic action. These latter effects are variable with the use of amrinone even when the hemodynamic measurements of output and filling pressures are improved. Nevertheless, although variable, the positive inotropic action apparently prevents systemic hypotension, which occasionally complicates the administration of pure peripheral vasodilators. Relative to inotropic and vasodilator effects, the dose-response curves for positive inotropic action and peripheral vascular smooth muscle relaxation may be different. Thus, at low doses, milrinone causes increments in cardiac contractility that tend to level off as the dose increases, while substantial vasodilation occurs with large doses of the agent.[33]

Potential for Altering the Natural History of Congestive Heart Failure: Need for Large Clinical Trials

CURT D. FURBERG, MD, SALIM YUSUF, MRCP, DPhil, and THOMAS J. THOM

Congestive heart failure (CHF) is a major clinical and public health problem; moreover, its incidence is increasing. Once this syndrome is manifest, the mortality rate is very high. To date, none of the drugs available for its treatment has been shown to reduce mortality. It is theoretically possible that in patients with overt CHF, drug treatment may not alter prognosis. This hypothesis suggests that patients at high risk of heart failure should be treated before CHF becomes manifest. Alternatively, the trials of patients with manifest CHF may have been unpromising, simply because they were too small. These considerations indicate an urgent need for very large studies of both categories of patients—a "prevention" trial in those without overt CHF and a "treatment" trial in those with overt CHF.

(Am J Cardiol 1985;55:45A–47A)

Congestive heart failure (CHF) is not a disease per se, but a common clinical manifestation of many different heart diseases in which there is extensive myocardial damage or poor left ventricular function. The 2 most common causes of this syndrome are atherosclerotic heart disease and hypertension, each of which contributes to about one-third of all cases. It is estimated that 2.3 million Americans suffer from CHF and approximately 400,000 new cases are diagnosed every year.[1] Because the prevalence of CHF increases with age and because patients with various cardiac diseases live longer owing to advances in medical and surgical management, the number of patients who develop CHF is expected to increase in the next few decades. This increase is already apparent. For example, the National Center for Health Statistics estimates that the number of hospital discharges for CHF (first listed and secondary diagnoses) almost tripled between 1970 and 1982 from 570,000 to 1,557,000.* In this report we discuss what is needed to reliably study the effect of drugs in reducing mortality in patients with CHF.

Effect of treatment on survival: Digitalis and diuretics are the mainstay of treatment for patients with CHF. Although these drugs were never shown to improve survival, they undoubtedly are effective in relieving some of the symptoms. Indeed, many cardiologists view these agents as indispensable; thus the sort of studies required to evaluate their effects on survival may never be undertaken. Because the information on digitalis and its effect on mortality is inadequate, the efficacy and safety of digitalis are under a cloud,[2] despite its use in several millions of patients over two centuries.

There have been several trials of other agents. Furberg and Yusuf[3] reviewed data from all available placebo-controlled trials of long-term vasodilator treatment in patients with CHF to evaluate whether these drugs can improve survival. We identified 18 published or unpublished randomized studies in which various vasodilators—α-adrenergic blockers, isosorbide dinitrate, hydralazine, minoxidil and angiotension converting enzyme inhibitors—were evaluated. All the trials were far too small to detect even large reductions in mortality and in only 1 study were patients treated for longer than 6 months. The largest trial enrolled only 106 patients. Most trials included patients who were functionally in New York Heart Association classes II to IV. The combined data from the trials of angiotensin converting enzyme inhibitors (captopril and enalapril) appear particularly promising and suggest that large long-term trials of this type of agent are justified. Thus, it appears timely to undertake trials of sufficient scope to determine whether treatment of CHF improves survival. We focus on the main considerations that go into the planning of such trials.

Selection of the study population: The incidence of CHF is highly age-dependent. Unpublished data from the National Center for Health Statistics' hospital

discharge survey (Table I) show that for both men and women, hospitalization rates are about 10-fold higher for those aged 75 years or over compared to the youngest group aged 45 to 64. Thus, the criterion for age eligibility in a trial will substantially influence potential recruitment, and enrollment of patients up to the age of 80 years should be considered. Further, any trial ought to consider both men and women for enrollment, as patients of either sex demonstrate a substantial incidence of CHF.

It is also important to consider the optimal time for initiation of treatment. The general experience from prevention trials in the cardiovascular field indicates that early intervention is more successful than late intervention. This is illustrated by some results from the Hypertension Detection and Follow-Up Program.[4] Referred-care participants with diastolic blood pressure between 90 and 104 mm Hg and end organ manifestations (history of myocardial infarction, stroke, intermittent claudication, left ventricular hypertrophy or creatinine levels 1.7 mg/dl) had a 5-year mortality rate of 17.8%, or more than 3 times that of participants with no such manifestation (5.6%). However, stepped-care therapy in this diastolic blood pressure stratum reduced the mortality rate by 27% in the group without end organ manifestations, compared to a reduction of approximately 7% in the group with such manifestations.

Types of trials: In principle, 2 kinds of trials can be conceived: prevention trials and treatment trials. A prevention trial enrolls patients free of overt CHF but at high risk for subsequent development of CHF. An advantage of such a trial in patients with no or only mild symptoms of CHF is that it could have a placebo group. A treatment trial, by contrast, enrolls patients who already are symptomatic. In such a trial, patients with various underlying pathologic conditions (hypertension, coronary artery disease or cardiomyopathy) are included. Randomization could be stratified within each of these groups to assess if even in advanced heart failure, etiology determines whether a treatment is beneficial or not. To this end, heterogeneity in patient selection is very useful. Such a trial would, by necessity, be based on a comparison of active treatments or a placebo-controlled study of an agent added to standard therapy. Both the prevention and treatment trials would have all-cause mortality as the outcome of primary interest.

Sample size considerations: In order to gauge sample size for a trial, 3 important considerations should be addressed: (1) What is the likely mortality rate in the control group? (2) What is the likely benefit? Or more appropriately, what is the smallest benefit that should not be missed? (3) What is the compliance likely to be?

To predict what the control-group mortality rate is likely to be, one should review data from previous observation studies and from other trials (if there are any). The mortality rate observed in these studies is then generally used as the expected control-group mortality rate. However, using this approach, the actual mortality rate in most large scale trials has been about 20 to 40% lower than expected (Yusuf and Friedman, unpublished observations). When this occurs, the "power" of a study is substantially reduced. This lower than expected mortality rate is due in part to the restricted inclusion of only "eligible" patients, and in part because some of the highest risk patients are electively treated and therefore excluded. Thus, we prefer to moderate our expectations of whatever mortality rate is suggested by previous studies. For example, if a 30 to 35% mortality rate is observed in particular types of patients in a study, our expectations in a trial would be about 20 to 25%. In the Coronary Artery Surgery Study, patients with an ejection fraction of less than 0.35 had a 3-year mortality rate of 45% if they were symptomatic and 22% if asymptomatic. Therefore, one would predict that in a prevention trial of asymptomatic patients with an ejection fraction less than 0.35, the mortality rate at 3 years would be 16 to 18%, and in a treatment trial of symptomatic patients with the same ejection fraction, the mortality rate would be about 30% over 3 years.

Estimating what treatment benefits are likely to be observed in a trial is even more hazardous, even when pilot studies exist. Only moderate benefits have been observed in mortality rates with most cardiovascular treatments, including surgery.[5] Thus, experience does not lead us to expect big effects, e.g., 40 to 50%, but instead more moderate reductions, 20 to 25%, in mortality rates. If these estimates appear unduly pessimistic, it should be noted that widespread use of a drug that reduces the risk of death in patients with CHF by about 20% would save 30,000 to 40,000 lives per year in the U.S. alone. Further, any trial that produces convincing evidence before the end of the planned follow-up period because of unexpectedly greater benefit can always be terminated ahead of schedule.

As in most trials of prolonged treatment, one would expect about 20 to 30% of patients to discontinue active treatment because of side effects or other reasons, and about the same number of patients initially assigned to control to start the active agent over the 3 to 4 years of the trial. This has the effect of further reducing any observed benefit.

These considerations suggest that about 4,000 patients are required for a 2-armed prevention trial and about half this number for a treatment trial. Because this combined number appears formidable and is about 10 to 20 times larger than any study of CHF completed thus far, the design of the main study would have to be

TABLE II Instantaneous and Noninstantaneous 25-Month Mortality Rates (%) by Risk Group and Treatment in the β-Blocker Heart Attack Trial

Complication	Propranolol	Placebo	Relative difference (%)
	Instantaneous Death		
None	1.7	1.9	12
Electrical only	2.5	5.0	50
Mechanical	3.1	6.0	49
	Noninstantaneous Death		
None	4.5	4.6	5
Electrical only	2.7	5.9	54
Mechanical	8.7	11.0	21

streamlined to make it practicable. Such a study could still provide information on questions other than mortality by incorporating detailed investigations in some subsets of patients.

Selection of intervention: It seems reasonable to propose testing a single drug—a vasodilator or perhaps an inotropic agent—in a prevention trial in coronary patients free of symptoms of CHF but with a low ejection fraction. On the other hand, in a treatment trial a combination of drugs or a "step-up" treatment schedule seems advisable. Past efforts to test single drugs in survival trials of patients with advanced coronary disease were generally not rewarding. An intriguing possibility is to combine the treatment of CHF with an antiarrhythmic agent, since it is known that almost half of the patients with overt heart failure die suddenly. Recent data from the Beta-Blocker Heart Attack Trial lend support to the idea of combination therapy (Table II). In this study, treatment with β blockers substantially reduced sudden death in patients with moderate left ventricular dysfunction (mechanical failure), presumably through an antiarrhythmic mechanism.[6] Alternatively, combining an inotropic agent with a vasodilator may be beneficial. If the question of combination therapy is to be actively pursued, a factorial design may be appropriate for assessing the effect of each component.

In summary, randomized controlled trials on the effect of drug treatment on survival in patients with CHF are feasible using a collaborative approach. Such trials are necessary before the use of the newer vasodilators and inotropic agents, which appear promising, becomes widespread. Two kinds of trials should be considered: first, a placebo-controlled trial of high-risk patients with no manifestations of CHF, in an attempt to prevent progression to overt heart failure and death (prevention trial); second, a trial of patients with overt CHF, to evaluate the effect of a new vasodilator or inotropic agent over and above standard therapy on mortality (treatment trial). To have reasonable power of detecting important differences, these studies should include about 4,000 asymptomatic and about 2,000 symptomatic patients. To be practicable, a relatively streamlined protocol is required. Other questions besides mortality could be assessed reasonably in smaller subsamples of the study patients.

Calcium-Channel Blockers: Present Status and Future Directions

Introduction

STEPHEN E. EPSTEIN, MD, DOUGLAS R. ROSING, MD, and C. RICHARD CONTI, MD

Since the original description by Fleckenstein in 1967 of an agent that manifested effects on conduction tissue apparently compatible with "calcium antagonist" actions, a veritable explosion of investigations has taken place. The calcium antagonists—or, as more currently referred to, the calcium-channel blocking agents—have been used as molecular probes to determine both the basic physiologic and pathophysiologic workings of tissues and organs, and as clinical agents to treat a wide variety of diseases.

This symposium was conceived so that experts in the basic and practical applications of calcium-channel blocking agents could be brought together to discuss the many aspects of this very complex field. The 28 articles in this symposium represent the fruit of that conference, which took place November 17 to 19, 1983. The symposium includes reports that deal with the basic cellular mechanisms responsible for the actions of calcium-channel blockers, including the effects of inhibiting calcium fluxes on excitatory and conducting tissues, on smooth muscle cells of blood vessels and of the gastrointestinal tract and on platelet function. The basic mechanisms modulated by calcium fluxes are also discussed in the context of diverse disorders that often are, or may be, responsive to the calcium-channel blockers, such as angina pectoris, coronary vasospastic disorders, cardiac arrhythmias, systemic hypertension, atherosclerosis, dilated and hypertrophic cardiomyopathies, abnormal cardiac diastolic function, migraine, subarachnoid hemorrhage, esophageal dysfunction and Raynaud's syndrome. In addition, the role of abnormal calcium fluxes in causing cellular damage during ischemia involving myocardium and neural tissues is considered, as is the potential use of calcium-channel blocking drugs in the treatment of myocardial infarction and stroke. Other articles explore the uses of these drugs in preserving myocardium during cardiopulmonary bypass, and in the treatment of pulmonary hypertension and asthma.

This symposium is the result of the thought, effort and studies of many persons. We hope that it will provide a stimulus for further studies that will permit a more fundamental understanding of the processes controlling both normal and abnormal cellular functions, and provide information leading to the more effective clinical use of calcium-channel blocking drugs.

Basic Cellular Mechanisms of Action of the Calcium-Channel Blockers

ARNOLD M. KATZ, MD

Calcium-channel blockers inhibit the entry of calcium ion (Ca^{++}) into excitable cells, including those of coronary and peripheral arterial smooth muscle and the heart. The ability of these drugs to block Ca^{++} entry into cells inhibits the essential role of this cation as an intracellular messenger. The effects of calcium-channel blockers on the heart include a negative inotropic effect on the working myocardial cells of the atria and ventricles. Because the upstroke of the action potential in these regions of the heart, and in the rapidly conducting cells of the His-Purkinje system, is due to a fast, sodium-dependent ionic current, calcium-channel blockers do not inhibit conduction in these cells. In the sinoatrial and atrioventricular (AV) nodes, on the other hand, depolarization is due primarily to a Ca^{++}-dependent slow inward current; as a result, the calcium-channel blockers inhibit the sinus pacemaker and AV conduction. Because our knowledge of the molecular structure of the calcium channels in the heart and smooth muscle is rudimentary, little is known of the molecular mechanisms by which calcium-channel blockers inhibit Ca^{++} entry across the sarcolemmal membranes in these cells. It is apparent, however, that the actions of different members of this class of drugs on the sarcolemma are not the same. Indirect evidence indicates that some members of this class of drugs may interact with hydrophobic regions of the proteins that make up, or regulate, the calcium channels in the plasma membrane. Work now in progress to define the precise sites of action of these drugs holds promise for the future development of new blockers with enhanced selectivity for calcium channels in specific cell types, making it possible to inhibit excitation-contraction or stimulus-secretion coupling in a given organ.

(Am J Cardiol 1985;55:2B–9B)

Calcium-channel blockers represent a new class of drugs that have found wide acceptance in the treatment of cardiovascular diseases. Unlike other currently available drugs, the therapeutic actions of these agents arise from their ability to inhibit directly the influx of calcium ion (Ca^{++}) across the plasma membranes of excitable cells. In the cardiovascular system, inhibitory effects are found in arterial smooth muscle—both coronary and peripheral—as well as in the heart. Because they affect tissue other than the heart and vasculature, calcium-channel blockers have considerable potential for use in other diseases.

The basis for these effects lies in the ability of these drugs to block Ca^{++} entry into cells, and thus to prevent this critical messenger from reaching sites within the cell that initiate, or regulate, key cellular processes. Because Ca^{++} is prevented from serving its essential role as an intracellular messenger, the term "calcium antagonist" is often used to describe these drugs. However, the calcium-channel blockers do not themselves antagonize the effects of Ca^{++}; instead, they prevent this ion from gaining access to its intracellular sites of action.

From the Division of Cardiology, University of Connecticut Health Center, Farmington, Connecticut. This study was supported in part by research Grants HL-22135, HL-21812 and HL-26903 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland.

Address for reprints: Arnold M. Katz, MD, Division of Cardiology, University of Connecticut Health Center, Farmington, Connecticut 06032.

Role of Calcium in the Cardiovascular System

Ca^{++} plays a key role in regulating the mechanical and electrical properties of both cardiac and vascular smooth muscle. This is because Ca^{++} serves both as a *chemical* signal that binds to proteins within the cell, and as the carrier of an *electrical* charge across the sarcolemma.

Calcium as a chemical messenger: In cardiac muscle, the role of Ca^{++} as an activator of contraction arises from its ability to initiate and modulate the interactions of the contractile proteins. These important functions of Ca^{++} are made possible by the very low Ca^{++} concentrations found within the resting myocardial cell, coupled with the presence in the cytosol of a family of high-affinity Ca^{++}-binding proteins. These proteins recognize the arrival of Ca^{++} within the cell

interior as a signal that generally either initiates or amplifies a cellular process.[1]

Ca^{++} also plays a central role in the initiation of smooth muscle contraction. As in the heart, this effect arises from the binding of Ca^{++} to a Ca^{++}-receptor protein of the contractile machinery. Ca^{++}-activated processes are also found in nonvascular smooth muscle and in a variety of nonmotile cells. The ability of the calcium-channel blockers to inhibit many of these Ca^{++}-dependent activation processes has been the basis for a growing number of clinical studies in which these drugs have been tested for their potential use to prevent or treat disorders arising from these Ca^{++}-activated processes.

Calcium as the carrier of an electrical signal: In addition to serving as a chemical messenger, the positively charged Ca^{++} carries an inward (depolarizing) current across the cardiac cell membrane.[2] The onset and decay of this current are slow, relative to the inward current carried by sodium (Na^+); hence this Ca^{++} current is often called the "slow inward current." In the working cells of the atria and ventricles, and in the rapidly conducting cells of the His-Purkinje system, Ca^{++} entry across the sarcolemma generates an inward current that contributes to the plateau of the action potential, which follows the primary depolarizing event arising from Na^+ entry through the fast inward current. In the pacemaker cells of the sinoatrial (SA) node and in the slowly conducting cells of the atrioventricular (AV) node, both of which lack active Na^+ channels, the inward current carried by Ca^{++} represents the major depolarizing mechanism. For this reason, Ca^{++} is responsible for normal pacemaker activity and AV conduction.

Provision of Activator Calcium in the Heart

During the process of excitation-contraction coupling, in which depolarization of the sarcolemma initiates contraction through the provision of Ca^{++} for binding to the contractile proteins, at least 2 mechanisms contribute to the appearance of activator Ca^{++} within the myocardial cell. A small amount of this ion moves across the sarcolemma from the extracellular space. This important activation process does not require the direct expenditure of energy because the Ca^{++} concentration in the extracellular space is approximately 10^{-3} M; during diastole, Ca^{++} concentration in the cytosol is approximately 10^{-7} M. The adult mammalian heart also contains a store of Ca^{++} in an intracellular membrane system, the sarcoplasmic reticulum (Fig. 1). Although the Ca^{++} concentration in the sarcoplasmic reticulum is not known with certainty, it is probably between 10^{-4} and 10^{-3} M and therefore much higher than that in the cytosol of the heart during diastole. Thus, as is the case of the flux of activator Ca^{++} across the sarcolemma, the movement of activator Ca^{++} out of the sarcoplasmic reticulum is a passive process.

According to one theory of excitation-contraction coupling, the influx of a small amount of Ca^{++} across the sarcolemma triggers a much larger Ca^{++} release from the sarcoplasmic reticulum ("calcium-triggered calcium release") that provides the large amount of Ca^{++} needed for binding to the contractile proteins and thus for the initiation of cardiac systole.[3,4]

Because both of the Ca^{++} fluxes that initiate cardiac systole are from a region of high Ca^{++} concentration (either in the extracellular space or in the sarcoplasmic reticulum) to one of much lower Ca^{++} concentration, the delivery of Ca^{++} to the cardiac contractile proteins is due largely to an increase in the Ca^{++} permeability of the sarcolemmal and sarcoplasmic reticulum membranes. It is generally assumed that these movements of Ca^{++} take place through "channels" that open in these membranes, as both of these membranes are themselves poorly permeable to this ion.

The complex nature of the mechanisms that regulate

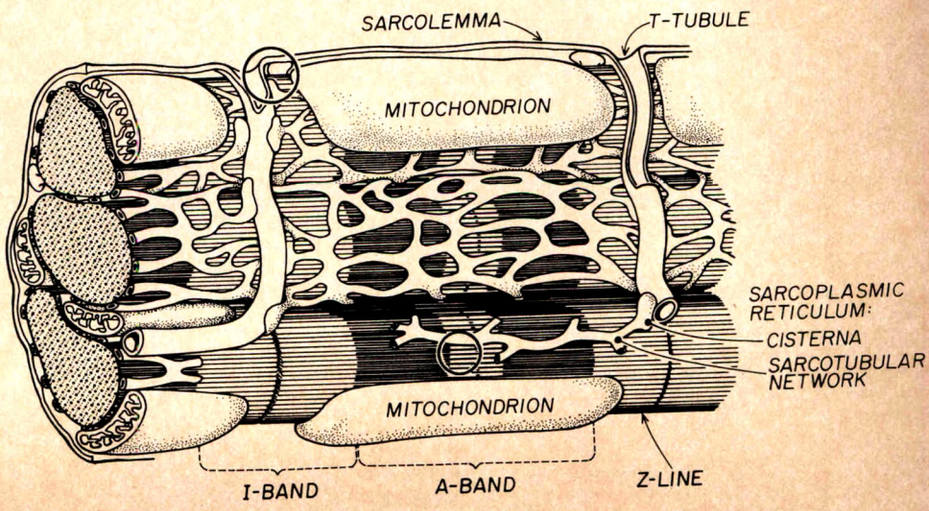

FIGURE 1. Ultrastructure of working myocardial cell. **Left,** contractile proteins are arranged in regular array of thick and thin filaments (cross-section). A-band represents region of sarcomere occupied by thick filaments into which thin filaments extend from either side. I-band is region of sarcomere occupied only by thin filaments; these extend toward center of sarcomere from Z lines, which bisect each I-band. Sarcomere, the functional unit of contractile apparatus, is region between each pair of Z-lines; it contains 2 half I-bands and 1 A-band. Sarcoplasmic reticulum, a membrane network that surrounds contractile proteins, consists of the sarcotubular network at center of sarcomere and cisternae, which abut on T-tubules and sarcolemma. Transverse tubular system (T-tubules) is lined by membrane that extends from sarcolemma and carries extracellular space into myocardial cell. Mitochondria are shown in central sarcomere and in cross-section at left. Reproduced with permission from *N Engl J Med* 1975;293:1184–1191.

the delivery of activator Ca^{++} to the cytosol is shown schematically in Figure 2, which contrasts the voltage-dependent calcium channels in striated muscle (Fig. 2A) with the more elaborate mechanism involving both voltage-dependent and receptor-operated calcium channels found in smooth muscle and nonmotile excitable cells (Fig. 2B). The top diagrams in both Figure 2A and 2B show the relatively simple mechanism by which activator Ca^{++} derived from the extracellular fluid reaches the cytosol by way of voltage-dependent calcium channels in the plasma membrane of striated muscle, or through either voltage-dependent or receptor-operated calcium channels in smooth muscle and nonmotile tissues.

More complex mechanisms involving activator Ca^{++} derived from intracellular stores are depicted schematically in the bottom part of Figure 2. In striated muscle (Fig. 2A), the release of activator Ca^{++} stored in the sarcoplasmic reticulum can be initiated by a small Ca^{++} entry (calcium-triggered calcium release, described earlier), or by a change in membrane voltage (depicted as Na^{+} entry through a sodium channel in the plasma membrane). Similarly, calcium release from an intracellular store in smooth muscle and nonmotile tissues can be initiated by an electrical signal or by Ca^{++} entry through voltage-dependent calcium channels as shown in the bottom part of Figure 2B. The calcium that initiates a calcium-triggered calcium release can also enter the cytosol of these tissues by way of receptor-operated calcium channels, and other messengers have been proposed to signal the release of calcium from intracellular stores.

Properties of the Calcium Channels in the Sarcolemma and Sarcoplasmic Reticulum

The membranes of the sarcolemma and sarcoplasmic reticulum are instrumental in controlling the Ca^{++} fluxes that are responsible for excitation—contraction coupling in the adult mammalian heart.[5] Each represents a barrier that separates the cytosol, in which maintenance of a low Ca^{++} concentration is essential for cell viability, from the regions of high Ca^{++} concentration in the extracellular space and the sarcoplasmic reticulum. Ion channels in both membranes regulate the "downhill" flux of Ca^{++} into the cytosol, although the properties of these ion channels and their sensitivities to calcium-channel blockers differ markedly.[6] The sarcolemmal and sarcoplasmic reticulum membranes also contain mechanisms that allow Ca^{++} to be transported from the cytosol into the extracellular space and lumen of the sarcoplasmic reticulum, respectively. As Ca^{++} transport out of the cytosol is against a concentration gradient, the mechanisms responsible for these active fluxes differ fundamentally from those that control passive Ca^{++} movements through the ion channels described previously.

Ca^{++} fluxes across the sarcolemma: The entry of Ca^{++} from the extracellular fluid is mediated by voltage-dependent ion channels in the sarcolemma, and by a sodium/calcium exchange mechanism. The latter in-

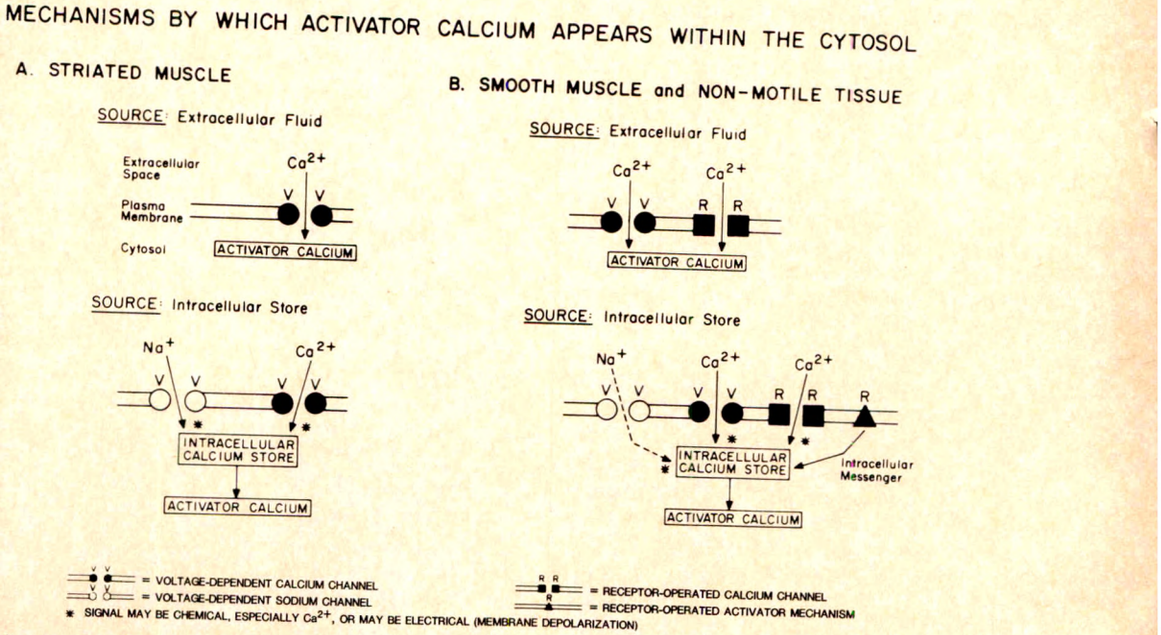

FIGURE 2. Schematic diagram showing mechanisms that can provide for delivery of activator Ca^{++} for excitation-contraction and stimulus-secretion coupling. (**A**) **Striated muscle:** in some amphibian and embryonic mammalian hearts, activator Ca^{++} is derived mainly from the extracellular fluid when this ion crosses the plasma membrane through voltage-sensitive calcium channels (**upper diagram**). In the adult mammalian heart (**lower diagram**), most of activator Ca^{++} is derived from intracellular stores in the sarcoplasmic reticulum from which Ca^{++}-release can be initiated when a small amount of this ion crosses the plasma membrane, or as a result of membrane depolarization. (**B**) **Smooth muscle and nonmotile tissue:** activator Ca^{++} derived from the extracellular fluid (**upper diagram**) can enter the cell through voltage-dependent calcium channels, one or more types of receptor-operated calcium channels or both. In many of these cell types, all or a portion of the activator Ca^{++} is derived from intracellular stores (**lower diagram**). Release of activator Ca^{++} from these stores can be induced by Ca^{++} entry through voltage-dependent or receptor-operated calcium channels, by membrane depolarization (which itself can be due to a calcium current), by other intracellular messengers released by plasma membrane or by any combination of these mechanisms.

volve a putative carrier that can bind either 1 Ca^{++} or 2 to 3 Na^{+} ions, and is able to move both cations in either direction across the sarcolemma. In addition to sodium/calcium exchange, which represents the most important mechanism that transports Ca^{++} out of the myocardial cell, the cardiac sarcolemma contains an adenosine triphosphate (ATP)-dependent Ca^{++} pump that directly links the liberation of chemical energy of ATP to the active transport of Ca^{++}.

As has already been discussed, Ca^{++} influx through the sarcolemmal-calcium channels represents a passive ion flux in which the cation moves down an electrochemical gradient from a region of high activity outside the cell to a region of low Ca^{++} activity within the cell. Sodium/calcium exchange, on the other hand, represents a countertransport mechanism in which the movement of 1 calcium ion in either direction is coupled to the movement of 2 or, more likely, 3 sodium ions in the opposite direction across the sarcolemma.[7] In this way, active Ca^{++} efflux from the cytosol is made possible by the energy derived from the downhill Na^{+} entry into the cytosol. This Na^{+} is pumped out of the cytosol by the sodium pump (Na-K ATPase).

Neither the calcium channel, the sarcolemmal Ca^{++} pump nor the putative sodium/calcium exchange carrier has been purified from cardiac muscle, so the biochemical properties of these transport mechanisms can only be deduced from the physiologic and pharmacologic properties of the transport processes themselves.

Ca^{++} fluxes across the sarcoplasmic reticulum: The mechanisms responsible for Ca^{++} fluxes across the intracellular membranes of the sarcoplasmic reticulum differ from those found in the sarcolemma. As is the case for the active transport of Ca^{++} across the sarcolemma, the sarcoplasmic reticulum contains an ATP-dependent Ca^{++} pump.[8] It appears, however, that these 2 Ca^{++} pumps are not the same. Much less is known of the mechanism by which this ion moves passively out of the sarcoplasmic reticulum.[9]

Structural Features of the Voltage-Sensitive Calcium Channel in the Sarcolemma

The membranes that control the movements of Ca^{++} from one region of the heart to another must possess 2 functional properties: they must provide a barrier that impedes the free movement of the ion between aqueous compartments, and they must contain structures that permit Ca^{++} movements from one side of the membrane to the other. As we shall see, much more is known of the structure of the barrier than of the mechanisms that control the movements of this ion across the barrier.

The membrane bilayer: The Ca^{++} impermeable barriers that separate the aqueous compartment of the cardiac cell interior (the cytosol) from those of the extracellular space and interior of the sarcoplasmic reticulum are lipid bilayers composed of phospholipid molecules. These bilayers can be viewed as ion-impermeable lipid sheets that are lined on either side by charged groups that interact readily with the aqueous compartments on either side of the membrane. Within the bilayer is a highly hydrophobic region, made up of hydrocarbon chains of the fatty acid moieties of membrane phospholipids, that serves very effectively to restrain the movements of ions such as Ca^{++}.

At the present time, most important biologic properties of a membrane, including the ability to transport ions, can be attributed to the proteins that lie within the bilayer. These intrinsic membrane proteins, which are firmly attached to the membrane bilayer, contain both hydrophylic regions that interact with the aqueous environments on either side of the membrane, and hydrophobic regions that are bound firmly within the hydrophobic fatty acyl chain region of the bilayer. These proteins can be imbedded in either half of the bilayer or, as is probably the case for ion pumps and channels, can span the bilayer so as to contact the aqueous compartments on both sides of the membrane.

Functional States of the Sarcolemmal Calcium Channels

The most important pathway for Ca^{++} entry across the sarcolemma is through calcium channels whose opening, closing and reactivation are under the control of the electrical potential across the membrane. Because the transitions between the open, closed and inactive states of these calcium channels are determined by membrane voltage, they are referred to as "voltage-dependent" channels. In addition to this voltage dependence, the transitions of the calcium channels in the cardiac sarcolemma at any membrane potential are governed by the intrinsic properties of the channel. Thus, the transitions of these channels are also "time dependent."

The time-dependent transitions in the cardiac sarcolemmal Ca^{++} channels are much slower than those of the fast sodium channels that are responsible for the initial depolarizing Na^{+} current in the working cells of the atria and ventricles, and in the rapidly conducting cells of the His-Purkinje system. For this reason, these calcium channels are often referred to as "slow channels."

The calcium channels of the cardiac sarcolemma differ from the sodium channels in another important respect—the voltage at which they begin to undergo their transition from the closed to the open state. Less depolarization is needed to initiate opening of the sodium channels than of the calcium channels. As a result, the calcium channels in the cells of the working myocardium and the His-Purkinje system begin to open only after the cell has already been partially depolarized by the rapid entry of Na^{+} through the sodium channels.

The working cells of the atria and ventricles and the fast conducting cells of the His-Purkinje system contain both sodium and calcium channels. In these cells, the delayed opening of the calcium channels, along with their relatively slow kinetics, cause the calcium channels to remain open after the initial, Na^{+}-dependent upstroke of the action potential has ended. In this way, the calcium channels generate an inward current that contributes to the plateau phase that is characteristic of the cardiac action potential in these regions of the heart. The fact that calcium channels are relatively insensitive to partial membrane depolarization, which can inactivate sodium channels, may permit the calcium

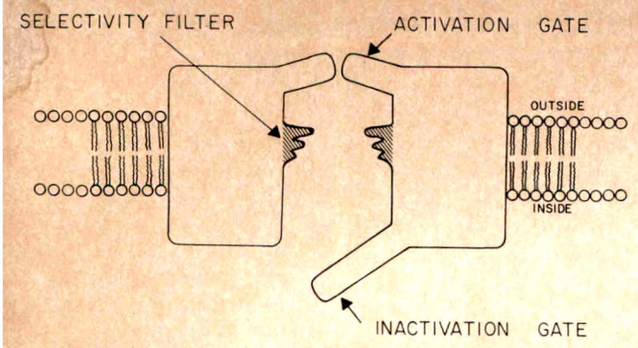

FIGURE 3. Schema of voltage-dependent ion channel in myocardial sarcolemma. The nature of the ion that can pass through open channel is determined by a "selectivity filter." Access of ions to channel is controlled by 2 different gating mechanisms. An "activation gate," which is closed in the resting state, opens in response to a change in transmembrane potential, thereby allowing ions to cross membrane. Closure of an "inactivation gate," which occurs at a slower rate in response to the same electrical signal that causes the activation gate to open, terminates the ion flux and inactivates the channel. The channel is reactivated when the activation gate has closed and the inactivation gate has reopened, both of which occur through voltage- and time-dependent processes. Reproduced with permission from *Am Heart J.*[12]

channels to initiate an action potential in partially depolarized cells, for example, in ischemic regions of the myocardium.

In the SA and AV nodes, where sodium channels are either absent or nonfunctional, the inward current carried by the calcium channels is entirely responsible for the action potential. This important feature, of course, determines the susceptibility of the sinus pacemaker and AV conduction to the effects of drugs that selectively block calcium channels.

Although some structural details are available regarding both the calcium pump of the sarcoplasmic reticulum,[10] which may also serve as a Ca^{++} channel,[9] and the rather nonselective channels connecting the interiors of adjacent cells across the nexus of the intercalated disk,[11] little is known of the structure of the voltage-sensitive ion channels of the cardiac sarcolemma. Several physiologic properties of these channels, however, allow certain key features to be schematized (Fig. 3).[12]

In view of evidence that these channels are highly specific for a given ion species, it can be assumed that the aqueous "pore" within the channel is provided with a selectivity filter that defines the type of ion that can pass through a given type of channel. Although the structure of the voltage-dependent calcium channels that generate the cardiac action potential is not known, their physiologic behavior gives some clues as to their molecular nature. In formulating a molecular model of an ion channel, the channel must be provided with a selectivity filter that determines its selectivity for the passage of a particular ion species (Fig. 3). In several cases, open ion channels appear able to contain more than one ion at any time. Thus, the passage of the ions through the channel can be viewed as the movement of a single file of ions, several of which are present at any time within the open channel.[13] Because the ions appear to move through the channel in their hydrated form, each open channel can contain several water-surrounded ions. One implication of this model is that the ion channel contains a series of barriers that interact with the hydrated ions as they pass from one side of the membrane to the other.

Because voltage-dependent ion channels can exist in different states, both open and closed, the model shown in Figure 3 is provided with "gates" that control the access of ions to the pore that crosses the membrane.

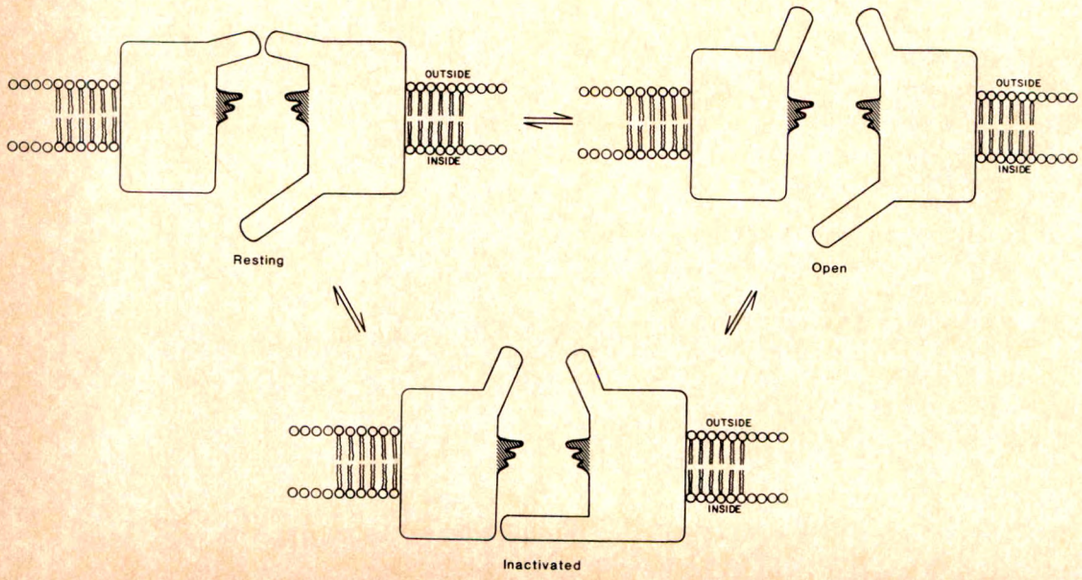

FIGURE 4. Three states of a voltage-sensitive ion channel are shown schematically using the diagram in Figure 3. In the resting channel, the activation gate is closed while the inactivation gate is open. A change in transmembrane potential initially opens the activation gate, thereby allowing ions to pass through the open channel. Subsequent closure of the inactivation gate causes the channel to become inactivated. Termination of the refractory state of the inactivated channel occurs when return to resting potential causes the inactivation gate to reopen and the activation gate to close. Reproduced with permission from *J Cardiovasc Med* 1983;8:435–452.

These gates appear to be charged regions of the channel proteins, because their ability to respond to changing transmembrane potential can be explained by the movement of charged structures in response to an alteration of the electrical field across the membrane. This hypothesis is supported by the ability of electrophysiologists to measure "gating currents." These currents, which are measured when membrane potential is abruptly changed under conditions in which transmembrane ion currents are eliminated, can be explained by the movement of charged structures within the membrane.[14] Thus, the opening and closing of the gates that control the access of ions to the interior of the transmembrane pore during the cardiac action potential can be explained by conformational changes of the channel proteins that result from the movements of charged regions of intrinsic membrane proteins comprising the ion channel.

To explain the physiologic properties of the voltage-dependent calcium channels of the cardiac sarcolemma, it is convenient to consider 3 states of the channel: resting, open and inactivated (Fig. 4). In the resting and inactivated states, Ca^{++} is unable to cross the membrane; in the open state, the gates are open and Ca^{++} can cross the membrane.

In the model shown in Figure 4, the movements of 2 types of gate are shown to control the transitions between these states of the channel. In the heart, calcium channels are closed when the cell is in its resting state and the interior of the cell is electronegative relative to the extracellular space. This resting state of the channel is shown with an *activation gate* closed and an *inactivation gate* open. Decrease of membrane potential, for example, when the approach of a propagated wave of depolarization or Na^+ entry through the fast inward current decreases electronegativity in the cell interior, causes the activation gate to open. This may be due to movement of a charged region of the channel, as has just been described. Once the channel is in its open or activated state, Ca^{++} ions can cross the membrane.

The open state of the calcium channel of the cardiac sarcolemma is quite brief and ends when, in response to sustained membrane depolarization, the inactivation gate closes the channel. However, the closed state of the calcium channel that terminates its open state differs from that of the resting channel. From a physiologic standpoint, the most important difference between these closed states is that in the resting cell membrane, the channel can open in response to membrane depolarization, whereas in the closed state that follows channel opening, the channel has become inactivated, or refractory, and can no longer open when the membrane is depolarized.

The inactivation gate is shown in the interior of the membrane in Figures 3 and 4, because it has been found in some cells that proteolytic enzymes added within, but not outside the cell can destroy the ability of the channel to become inactivated. According to this model, the transient opening of the calcium channel occurs during the brief interval between the rapid opening of the activation gate and the slower closing of the inactivation gate, both of which are initiated by membrane depolarization.

The return of the channel to its resting state does not occur until the resting membrane potential is restored and the interior of the cell is again electronegative. In the case of the calcium channels of the cardiac sarcolemma, this is brought about by the movement of potassium ions (K^+) out of the cell through its own K^+-selective channels. There is evidence that some of these repolarizing K^+ currents are initiated, or accelerated, by the appearance of Ca^{++} within the cell.[15] Once the cell interior again becomes electronegative, both the activation and inactivation gates return to their original resting states, thereby terminating the refractory state of the channel.

The voltage-dependent transitions of calcium channels in the cardiac sarcolemma are, in general terms, similar to those of the sodium channels that produce the initial rapid upstroke of the action potential in the cells of the His-Purkinje system and working atrial and ventricular myocardium. As has already been pointed out, however, the calcium and sodium channels differ in 2 important ways[16]: less depolarization is needed to activate and inactivate the sodium channels, and the rates of activation, inactivation and reactivation of the calcium channels are much slower than those of the sodium channels. Because conduction velocity is directly proportional to the rate of depolarization, propagation of Ca^{++}-dependent action potentials is slower than that of Na^+-dependent action potentials.

It must be emphasized that the model in Figures 3 and 4 is highly conjectural, and that other quite different models can also explain the physiologic properties of these channels.[17,18]

Actions of Drugs on the Calcium Channels in the Cardiac Sarcolemma

Several mechanisms have been proposed to explain the effects of drugs on calcium channels in the myocardium. From a molecular standpoint, perhaps the best understood are those caused by agents that increase cellular levels of adenosine 3′:5′-cyclic phosphate (cyclic AMP). These are probably mediated when the channel protein, or a protein that regulates its function, is phosphorylated by cyclic AMP-dependent protein kinases. In the case of the mechanism by which cyclic AMP regulates Ca^{++} transport across the membrane of the sarcoplasmic reticulum, phosphorylation of a 22,000 dalton protein called phospholamban leads to the acceleration of Ca^{++} fluxes carried out by the much larger, approximately 100,000 dalton, calcium pump ATPase protein.[19] There is also evidence that cyclic AMP-dependent phosphorylation increases the opening of calcium channels in the cardiac sarcolemma, although the molecular mechanism by which this occurs is poorly understood.[20]

In the case of calcium channels in smooth muscle and certain nonmotile excitable cells, the binding of neurotransmitters to their receptors can induce the opening of "receptor-operated channels." [21] Even less is known of the molecular basis for the operation of these channels than of the voltage-dependent channels described earlier. Clearly some sort of process is set into motion when an agonist binds to its receptor, but the nature of the molecular changes within the membrane that are

responsible for the eventual opening of a calcium channel is not known.

Another mechanism by which drugs are postulated to inhibit the flux of ions through a membrane channel is by insertion of the drug into the mouth of the channel. This mechanism has been proposed to explain the ability of membrane depolarization, which causes opening of the sodium channels, to enhance the potency of several antiarrhythmic drugs, including quinidine, that block these channels. A similar mechanism can explain the ability of verapamil and diltiazem to block calcium channels preferentially when the channels are in the open or inactivated state. This "use dependence" (that is, the potency of a drug to block the channels is enhanced when the channels have been "used") is most easily explained if the drugs enter the "mouth" of the channel preferentially during its open state. In the case of D600, an analogue of verapamil, evidence suggests that the drug binds preferentially at the inner, or cytosolic, opening of the calcium channel.[22]

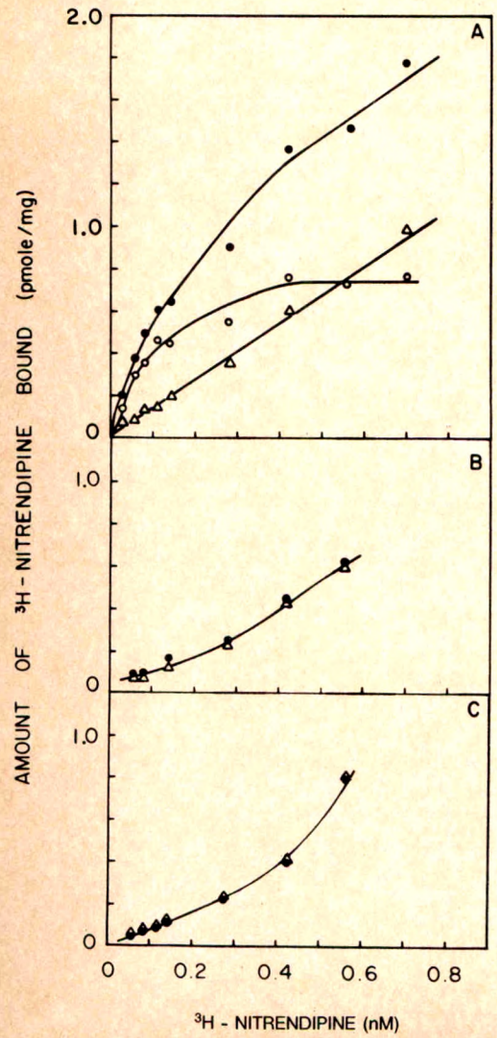

FIGURE 5. Total (**closed circles**), specific (**open circles**) and nonspecific (**open triangles**) binding of nitrendipine to (**A**) sarcolemmal, (**B**) sarcoplasmic reticulum and (**C**) mitochondrial membranes isolated from canine myocardium, as function of increasing concentrations of ^{3}H-nitrendipine. Reproduced with permission from *J Mol Cell Cardiol.*[25]

Yet another mechanism can explain some drug effects on the operation of sarcolemmal calcium channels. This is a nonspecific (local anaesthetic or "membrane stabilizing") action suggested by the hydrophobic nature of many membrane-active drugs, and involving interactions of the drug with hydrophobic regions of the membrane bilayer. These nonspecific interactions of a hydrophobic drug with the bulk membrane phospholipids can be mediated by incorporation of amphiphilic molecules into the membrane bilayer at regions remote from the intrinsic membrane proteins, where they may modify channel function through membrane expansion or other physical changes in membrane structure.[23] The resulting inhibition of channel function can thus be viewed as secondary to structural rearrangements within the membrane bilayer. Although hydrophobic interactions of drug molecules with the membrane bilayer can explain nonspecific effects of many drugs, they seem unlikely to explain *specific* actions of drugs on one or another class of membrane channels.

In contrast, the specific interaction of a drug with a given type of ion channel implies some recognition between the drug and the proteins that make up and regulate the channel. As has been indicated, these specific interactions could arise from a simple "plugging" of the channel mouth by the drug, or by a high-affinity interaction with a specific receptor site that is related to the channel. Because calcium-channel blockers often exert their actions at nanomolar concentrations, and stereospecificity has been observed,[24] it appears likely that they are recognized by specific structures of the calcium channel. The complexity of these interactions is highlighted by marked differences in the responses of Ca^{++} channels in different tissues, and even in the responses of different types of Ca^{++} channels in a given cell type, to a given calcium-channel blocking drug.[21] However, the wide variety of chemical structures that can block Ca^{++} channels more or less selectively argues against the tight binding of these drugs to a single class of "receptors" analogous to those that bind β-adrenergic agonists.

It is possible that the different chemical structures that share the ability to block calcium channels interact with hydrophobic regions of the channel proteins at sites in contact with the aqueous medium on the outside of the membrane. The large hydrophobic moieties of most of the calcium-channel blocking drugs, however, suggest that they may also interact with hydrophobic regions of the channel proteins, where they are imbedded in the fatty acyl chain region of the phospholipid bilayer. In either case, the changing sensitivity of the calcium channel to these drugs as the channel changes its state can be explained by a drug's preference for a given conformation of the channel. For example, verapamil's ability to block the channel is enhanced by prior depolarization of the membrane; this implies either that verapamil is bound within the open channel or that its strongest interaction with the channel proteins occurs when the channel is in its open state.

Differences in the susceptibility of various types of calcium channels to calcium-channel blocking drugs provides additional evidence for highly specific interactions between the calcium-channel blockers and the

structures whose function they inhibit. In general, receptor-operated calcium channels in smooth muscle, which open when a neurotransmitter or other agonist binds to its receptor on the sarcolemma, are less sensitive to these drugs than are voltage-dependent calcium channels that open in response to depolarization of the membrane.[21] As a result, excitation processes initiated by membrane depolarization are more likely to be inhibited by the calcium-channel blockers than would those excitation mechanisms that are mediated by neurotransmitters. As shown in Figure 2, however, the complexity and interplay of these mechanisms in smooth muscle make predictions based on this generalization rather risky.

Differences in sensitivity to the calcium-channel blockers are also found when similarly regulated calcium channels in different tissues are compared. For example, nifedipine is a much more potent blocker of voltage-dependent calcium channels in smooth muscle than in the heart; in contrast, the potency of verapamil in these 2 tissues is more similar.

The specific nature of the interaction between calcium-channel blocking drugs and cardiac membranes was demonstrated in a recent study from our laboratory that compared the ability of low concentrations of labeled nitrendipine, a calcium-channel blocker closely related to nifedipine, to bind to different membranes isolated from canine ventricles.[25] Nitrendipine bound specifically, and with high affinity, to sarcolemmal vesicles but not to membrane vesicles derived from the sarcoplasmic reticulum or to mitochondrial membranes (Fig. 5). This points to an interaction between nitrendipine and a structure present only in the sarcolemma, possibly the calcium channel itself or a protein involved in its physiologic regulation.

At present, few data allow the mechanism responsible for channel blockade to be defined in molecular terms. This question, however, is of considerable importance not only from its theoretical interest, but also from a practical standpoint. The practical implications of a clearer understanding of the molecular mechanism by which calcium-channel blockers exert their effects include the possibility that future research may allow calcium-channel blocking drug molecules to be "tailored" so as to block specific classes of calcium channel. This could lead to the development of drugs targeted to block calcium channels in one or another tissue. With such drugs, we would be able to inhibit specifically excitation-contraction or stimulus-secretion coupling in a given organ and so improve the specificity of treatment of diseases, like coronary vasospasm, that arise from abnormal calcium-channel function in one or another region of the body.

In conclusion, calcium-channel blockers inhibit Ca^{++} entry into excitable cells, including those of the coronary and peripheral arterial smooth muscle and heart. The ability of these drugs to block Ca^{++} entry into cells inhibits the essential role of Ca^{++} as an intracellular messenger.

The effects of the calcium-channel blockers on the heart include a negative inotropic effect on the working myocardial cells of the atria and ventricles. Because the upstroke of the action potential in these regions of the heart and in the rapidly conducting cells of the His-Purkinje system is due to a fast, sodium-dependent ionic current, the calcium-channel blockers do not inhibit conduction in these cells. In the SA and AV nodes, on the other hand, depolarization is due primarily to a calcium-dependent, slow inward current; as a result, the calcium-channel blockers inhibit the sinus pacemaker and AV conduction.

Our knowledge of the molecular structure of the calcium channels in the heart and smooth muscle is rudimentary, and little is known of the molecular mechanisms by which calcium-channel blockers inhibit the passage of Ca^{++} across the sarcolemmal membranes in these cells. It is apparent, however, that the actions of different members of this class of drugs on the sarcolemma are not the same. For example, nifedipine is much more potent as an inhibitor of calcium channels in smooth muscle than in the heart, whereas verapamil and diltiazem are approximately equipotent in the heart and vascular smooth muscle.

Although the precise molecular site of action of the calcium-channel blockers on the sarcolemma is not known, indirect evidence indicates that different members of this class of drugs act at different sites in these membranes, possibly with hydrophobic regions of the proteins that make up or regulate these channels.

Comparative Effects of Calcium-Channel Blocking Agents on Left Ventricular Function During Acute Ischemia in Dogs With and Without Congestive Heart Failure

JOANN URQUHART, MD, STEPHEN E. EPSTEIN, MD, and
RANDOLPH E. PATTERSON, MD

To examine the relative potencies of verapamil, nifedipine and diltiazem on left ventricular (LV) function under ischemic conditions, 20 conscious closed-chest dogs that had partial occlusion of their circumflex coronary arteries were studied. Myocardial blood flow was measured by microspheres, LV function by radionuclide angiography. Drug effects were compared at doses causing equal decreases in mean arterial pressure (MAP) and in coronary vascular resistance of the nonischemic zone. Global ejection fraction (EF) and EF of the ischemic region were significantly decreased by verapamil ($p < 0.002$) and increased by nifedipine ($p < 0.001$); diltiazem caused no significant changes. Verapamil significantly increased peak diastolic filling rate ($p < 0.001$); nifedipine also increased diastolic filling rate but only at doses that markedly decreased MAP and coronary vascular resistance. Diltiazem was not significantly different from placebo. For doses causing an equal decrease in MAP, verapamil decreased heart rate ($p < 0.001$), and diltiazem and nifedipine increased heart rate ($p < 0.05$). Myocardial ischemic zone flow remained unchanged during placebo, verapamil, diltiazem or nifedipine infusion. To study the influence of heart failure on the hemodynamic effects of the calcium-channel blocking agents, 6 foxhounds underwent total occlusions of the left anterior descending coronary artery, resulting in myocardial infarction, volume loading to increase left atrial pressure and partial occlusion of the circumflex coronary artery. Verapamil depressed global left ventricular ejection fraction and increased left atrial pressure to as high as 40 to 45 mm Hg. In contrast, nifedipine decreased left atrial pressure and increased global EF. To evaluate whether the negative inotropic effect of verapamil or the positive inotropic effect of nifedipine was beneficial or detrimental to ischemic tissue, intramyocardial pH in dogs that had regional myocardial acidosis after acute coronary occlusion was studied. Pretreatment with verapamil decreased the degree of acidosis of ischemic myocardium as it depressed LV function, whereas nifedipine caused no change in the degree of acidosis as it increased LV function. These findings suggest that the negative inotropic effects of verapamil can protect ischemic myocardium.

(Am J Cardiol 1985;55:10B–16B)

Verapamil, diltiazem and nifedipine are being used with increasing frequency in patients with angina pectoris caused by coronary artery disease. The antianginal mechanisms of these drugs remain uncertain, although they are known to have several hemodynamic and electrophysiologic effects that may contribute to their salutary actions. They are potent systemic vasodilators,[1] they possess negative inotropic potential[2] and verapamil and diltiazem can decrease sinus nodal automaticity and thereby decrease heart rate.[3–5] In addition, it is likely that varying degrees of coronary vasoconstriction may play a role in exacerbating coronary obstruction and thereby predispose the precipitation of angina pectoris in some patients with coronary atherosclerotic heart disease, even though they do not have severe coronary artery spasm.[6,7] Thus, the coronary vasodilator effects of calcium antagonists may also contribute to their antianginal effects.

Although each of the 3 calcium-channel blocking drugs approved for use in the United States exerts beneficial effects in patients with angina pectoris caused by coronary artery disease,[8–12] data have emerged suggesting that the relative potencies of these drugs

differ in terms of their physiologic actions, that is, their electrophysiologic, vasodilator and negative inotropic effects. For example, several investigators[5,13,14] have shown that verapamil and diltiazem decrease sinus nodal automaticity and prolong atrioventricular conduction, thereby causing bradycardia. Mitchell et al[15] showed that although verapamil and diltiazem produce equivalent slowing of atrioventricular conduction, verapamil prolongs atrioventricular nodal refractoriness to a greater degree. Nifedipine, in contrast, has no direct electrophysiologic effect; it usually reflexly increases heart rate secondary to its hypotensive actions. In addition, although all 3 calcium-channel blocking agents are systemic vasodilators,[1] nifedipine is more potent by at least 1 order of magnitude. This has been shown by both in vitro and in vivo studies.[16–19]

Nifedipine, verapamil and diltiazem all have intrinsic negative inotropic properties that are most clearly demonstrated in studies using isolated muscle preparations.[2,20] Data show that the intracoronary injection of calcium-channel blockers at doses causing no systemic vasodilatation also causes negative inotropic effects.[21] However, as is the case with their electrophysiologic and vasodilator actions, the relative negative inotropic potencies of these 3 drugs differ considerably. A summary of these differences follows.

In isolated muscle preparations, nifedipine has the strongest depressant effect per molar concentration.[2,20] These results do not agree with those of most clinical studies, which demonstrate that nifedipine has minimal, if any, negative inotropic action.[22–26] In the experimental animal, Henry,[21] Weintraub[27] and their coworkers even reported improved shortening of ischemic myocardial segments with nifedipine. On the other hand, Walsh et al[28] found that in conscious dogs nifedipine had the strongest negative inotropic effect, when compared with verapamil and diltiazem.

Such disparities illustrate some of the difficulties in assessing the inotropic potential of a given drug and the relative potencies of different drugs. For example, when calcium-channel blockers are administered to animals in which reflexes remain intact, the emergence of their negative inotropic potential may become masked because of the confounding effects produced by alterations in afterload and changes in reflex stimulation to the heart. In addition to the effects exerted by differences in loading conditions and the degree of reflex stimulation to the heart, the disparities observed among the aforementioned studies may also relate to differences in methods used in assessing inotropic state, preparing the agents and dose of agent used. For example, Walsh et al[28] used equimolar doses of nifedipine, verapamil and diltiazem to compare effects. This approach ignores the fact that nifedipine is a much more potent vasodilator than either verapamil or diltiazem; hence, the clinically relevant dose of nifedipine that should be used in comparative studies would be much lower, on a milligram per kilogram basis, then the doses of verapamil or diltiazem. In this regard, no clinical studies and few experimental ones have used a wide range of doses of each agent. This would have permitted a comparison of the effects of these agents on left ventricular (LV) contractile function using dose-response curves, or at least doses that produce equivalent decreases in arterial resistance or pressure.

Millard et al[29] did use equi-effective vasodilator doses of verapamil, nifedipine and diltiazem, and found in conscious dogs that nifedipine exerted a positive inotropic effect and verapamil a negative one; diltiazem exerted little effect on contractile function. These results are important, but the observations were limited to animals not having myocardial ischemia. Assessing the relative effects of these drugs during ischemia is critical, because they are frequently used in such situations, and because it has been shown that, whereas verapamil may cause selective depression of ischemic myocardium,[30] no such effects have been associated with administration of nifedipine.

To examine the relative potencies of verapamil, nifedipine and diltiazem on LV function under ischemic conditions, we studied 20 conscious, closed-chest dogs.[31] We used such a model to avoid the effects of anesthesia or acute surgical trauma and to maintain reflex responses intact. The circumflex coronary artery was partially occluded in each dog before therapy with either placebo, verapamil, nifedipine or diltiazem, and the partial occlusion was maintained throughout the study. The dogs were studied in the conscious state during control conditions in the absence of myocardial ischemia, and then during partial occlusion before and during 4 doses of either saline solution placebo or 1 of the 3 calcium-entry blockers infused intravenously. After a 2-minute duration of a loading dose, each of 4 doses was administered intravenously for about 15 minutes. Loading doses were 30 μg/kg/min for verapamil and diltiazem, followed by infusions of 5, 10, 20 and 40 μg/kg/min respectively, for doses 1 to 4. The loading dose for nifedipine was 5 μg/kg/min, followed by infusions of 1, 2, 4 and 6 μg/kg/min, respectively, for doses 1 to 4.

Five dogs were studied in the placebo group, and 5 in each of 3 drug treatment groups. Myocardial blood flow was measured by radioactive microspheres, and LV function was measured by electrocardiogram-gated radionuclide angiography. The consequences of ischemia due to partial coronary occlusion were similar in all 4 groups. This similarity was assessed by comparing the absolute and relative changes between control and partial occlusion states before drug administration for myocardial blood flow, ejection fractions (EFs) and hemodynamic features.[31] When each of the 7 measured variables was ranked from least (1.0) to greatest (4.0) effect of partial occlusion, the mean rankings were not different: placebo (2.6), verapamil (2.6), diltiazem (2.4) and nifedipine (2.4 rank order units). Drug effects were compared at doses causing equal decreases in mean arterial pressure, and at doses causing equal decreases in coronary vascular resistance of the nonischemic myocardium.

We found that the 3 drugs differed markedly in their effects on LV function, during both systole and diastole. Most important, these different effects were evident at doses of each drug that exerted identical effects on mean arterial pressure or on coronary vascular resistance.

Nifedipine increased global EF and EF of the ischemic zone in parallel with its vasodilator actions (Fig. 1 and 2). Verapamil, in contrast, decreased both global and ischemic zone EF (Fig. 1 and 2) at doses that produced a vasodilator effect identical to that of nifedipine. Furthermore, the drugs exhibited different relative potencies when the minimal threshold dose required to cause vasodilation, as measured by a decrease in coronary vascular resistance, was compared with the threshold dose required to alter myocardial contractile function and LV diastolic filling.

Thus verapamil depressed myocardial contractile function, even at a dose that was not sufficient to alter aortic pressure or coronary vascular resistance (Fig. 2), a finding suggesting that the myocardium during ischemia may be more sensitive to the calcium-inhibiting actions of this drug than is vascular smooth muscle. It also suggests that a clinically safe dose of verapamil, in terms of its myocardial depressant effect, cannot be predicted on the basis of the drug's lack of effect on arterial pressure. The improvement in EF caused by nifedipine throughout its dose-response curve suggests that nifedipine, at least during mild ischemia, exerts no physiologically important myocardial depressant actions, and indicates that the direct myocardial depressant effects of nifedipine evident in vitro[2] may only occur at doses that result in more marked hypotension than achieved in our study. Moreover, the threshold dose at which EF increased was the same as that at which vascular resistance decreased (Fig. 2), a finding compatible with the concept that improved EF observed after nifedipine administration is caused by the afterload-reducing capacity of the drug and reflex sympathetic stimulation of the heart. Thus the direct myocardial depressant effects of nifedipine may be overshadowed in the intact animal by these indirect effects on cardiac function.

Although diltiazem decreases global EF at doses producing large decreases in coronary vascular resistance (Fig. 2), neither global nor ischemic zone EF was altered at doses producing no more than a 10- to 15-mm Hg decrease in arterial pressure (Fig. 1 and 2). This suggests that diltiazem, when administered in doses producing physiologic changes in arterial pressure and coronary vascular resistance, does not exert any net depressant effect on normal or mildly ischemic myocardium. However, if diltiazem were devoid of myocardial depressant activity, EF would be expected to increase because of the concomitant decrease in afterload, as was found with nifedipine. Hence our findings suggest that diltiazem does have negative inotropic effects during myocardial ischemia, a finding also suggested by the increase in left atrial pressure caused by the drug, from 8.8 ± 5.1 mm Hg after occlusion to 15.3 ± 5.1 mm Hg during dose 4 (Fig. 3). However, these negative inotropic effects, which are milder than those

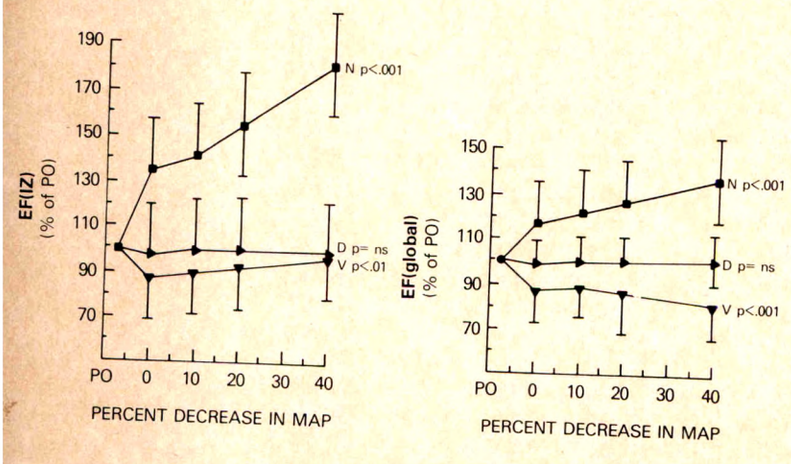

FIGURE 1. Comparison of drug effects at doses causing an equal decrease in mean arterial pressure (MAP). Ischemic zone (IZ) and global ejection fraction (EF) were increased by nifedipine (N), decreased by verapamil (V) and unchanged by diltiazem (D). **Bars** show 1 standard elevation. Change is presented as percentage of value during partial occlusion (PO) before drug administration. P values show results of analysis of variance in this and subsequent figures. FIGURE 2. Comparison of drug effects at doses causing equal decrease in coronary vascular resistance (CVR). Ischemic zone (IZ) and global ejection fraction (EF) were increased by nifedipine, decreased by verapamil (V) and unchanged by diltiazem (D) except at very high doses, causing depression of EF. Change is presented as percentage of value during partial occlusion before drug administration. Reprinted with permission from *Circulation.*[31]

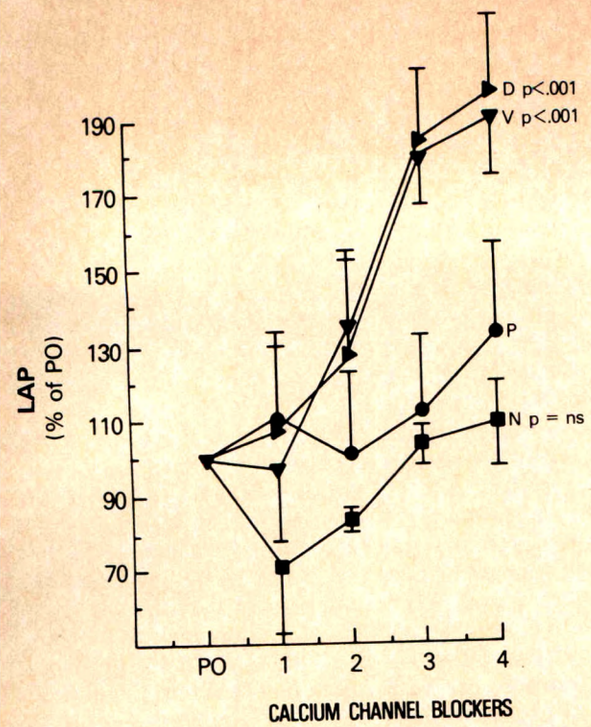

FIGURE 3. Comparison of dose response curves for left atrial pressure (LAP). Verapamil (V) and diltiazem (D) raised LAP compared with placebo (P). Nifedipine (N) was not different from placebo (P). Data are presented as percentage of value during partial occlusion before drug administration. Reprinted with permission from *Circulation.*[31]

of verapamil at doses causing comparable vasodilatation, are probably masked by the afterload-reducing actions of the drug and by the resulting sympathetic stimulation of the heart caused by baroreceptor reflexes.

In contrast to these results, Perez et al[32] found improved shortening of ischemic segments 20 and 80 minutes after total coronary occlusion in dogs treated with diltiazem to reduce aortic pressure by 5 mm Hg. Part of the difference between this study and ours may have been the use of open-chest versus awake closed-chested dogs. Further, Millard[33] noted improved shortening in the lateral border of normal tissue near an ischemic region (but not in the central ischemic region) with diltiazem in open-chest pigs; however, these borderline normal measurements are of uncertain significance.

It is also possible that our measurement of ischemic region EF by radionuclide angiography was less sensitive than the segment length measurements by ultrasound crystals used in those studies.[32,33] However, our measurements of ischemic regional function agreed with the ultrasound crystal method in studies of the effects of verapamil[30] and nifedipine.[21,27,32] Thus the different methods used to assess regional function may account for the difference between this and other studies[32,33] on the effects of diltiazem.

Differences in relative potencies of the 3 drugs on diastolic filling were also observed (Fig. 4). Partial coronary occlusion led to a marked impairment of peak diastolic filling rate, and verapamil administration led to large increases in the peak rate of diastolic filling. As with systolic cardiac function, verapamil improved diastolic filling at very low doses, that is, at doses that were insufficient to decrease mean arterial pressure or coronary vascular resistance. Although nifedipine also improved diastolic filling, it only did so at relatively higher doses, those that produced large decreases in mean arterial pressure and coronary vascular resistance. Further, the increases in diastolic filling rate produced by nifedipine was associated with a marked increase in heart rate, which by itself may increase diastolic filling rate. In contrast, the increase in diastolic filling rate produced by verapamil was associated with a decrease in heart rate. Diltiazem had no significant effect on diastolic function.

There is general agreement that verapamil, diltiazem and nifedipine increase coronary blood flow through normal coronary arteries as a result of vasodilation.[34–36] One of the most controversial areas, however, is the effect of calcium-channel blockers on coronary blood flow to ischemic myocardium. Henry et al[37] demonstrated an increase in myocardial blood flow to the lateral "border zone" with nifedipine, and interpreted this as representing an increase in collateral flow. This study did not consider the fact that the lateral border zone has been shown to be an admixture of normal and ischemic tissue, and therefore the increase in blood flow may in fact have represented an increase in flow to normal components of a sample composed of a mixture of nor-

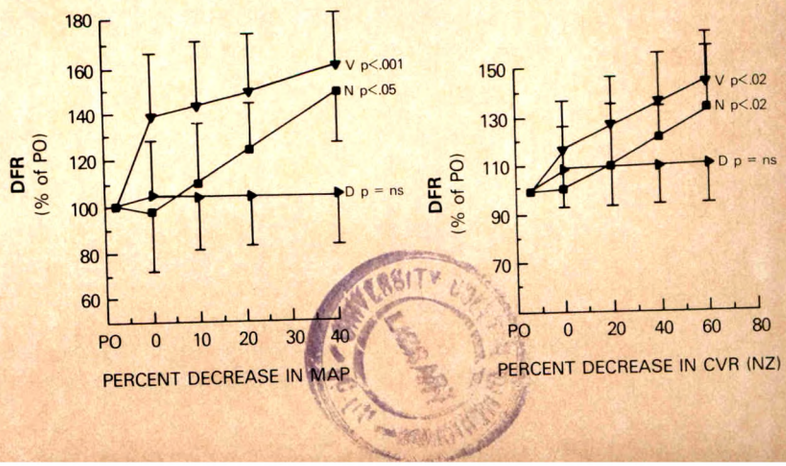

FIGURE 4. Comparison of drug effects at doses causing equal decrease in mean arterial pressure (MAP) and coronary vascular resistance (CVR). Verapamil (V) increased diastolic filling rate (DFR) at very low doses, whereas nifedipine (N) increased DFR only at high doses. Diltiazem (D) had no effect on DFR. Reprinted with permission from *Circulation.*[31]

mal and ischemic tissue.[38] Weintraub et al[39] took this admixture into account when analyzing their data from an open-chest model of partial occlusion, and showed that nifedipine increased subendocardial blood flow in the nonischemic zone, but decreased it in the ischemic zone. Bourassa et al[36] also used a model of partial occlusion and found that diltiazem increased coronary blood flow to the nonischemic area without changing flow to the ischemic tissue. These studies used models with total coronary occlusion, that is, regions of ischemia in which flow from collateral vessels may play an important role. Such results are probably not applicable to models of partial coronary occlusion, in which flow from collateral vessels probably plays a minor role.

We studied coronary blood flow in a model of partial occlusion in conscious dogs using a wide range of doses. Coronary vascular resistance in the normal zone did not change after partial coronary occlusion or during placebo infusion; however, it decreased significantly ($p < 0.001$) with nifedipine, verapamil and diltiazem (Fig. 5). Myocardial blood flow to the ischemic region measured by microspheres during partial coronary occlusion was 0.23 ± 0.03 ml/min/g, which was 18% of the blood flow to the normal zone. Ischemic zone flow remained unchanged during placebo, verapamil, diltiazem or nifedipine infusion (Fig. 5). Partial coronary occlusion decreased the ratio of subendocardial to subepicardial blood flow similarly in all groups, and no drug caused any significant changes in this ratio.

The lack of effect on flow to ischemic myocardium during partial coronary occlusion was most likely due to the fact that the arterioles of the ischemic zone were already maximally dilated and were therefore not susceptible to further dilatation. A second explanation may be that we studied the actions of these drugs under physiologic conditions, so that we made no attempt to control either arterial pressure (and thereby the distending pressure on the coronary artery) or heart rate. Decreases in the distending pressure of the coronary artery, particularly in partially occluded arteries, can cause passive increases in the resistance of the large epicardial artery.[40] Hence, it is possible that the coronary arterioles were dilated by the calcium-entry blocking agents, but that the resulting effect on total coronary vascular resistance was overridden by a concomitant passive increase in large vessel resistance caused by the decrease in coronary distending pressures.

Also, there usually is marked variability in myocardial blood flow when microsphere techniques are used.[41] This is particularly true when flow is measured in ischemic tissue.[42] This variability means that small changes in flow might be induced by these agents but they could not be detected by this technique. However, the direction of flow change after the administration of each drug was for blood flow to ischemic myocardium to decrease, although the changes were not significant. Thus in this model the calcium-entry blocker definitely did not improve blood flow to myocardium supplied by a fixed partial coronary occlusion.

We conclude that the relative potencies of the 3 calcium-channel blocking agents on LV systolic and diastolic function during myocardial ischemia are different when compared at the same level of vasodilator effect. Because verapamil and diltiazem depress myocardial contractility in the intact organism, even in the presence of only mild ischemia, their usefulness in the treatment of angina pectoris might sometimes be hazardous in

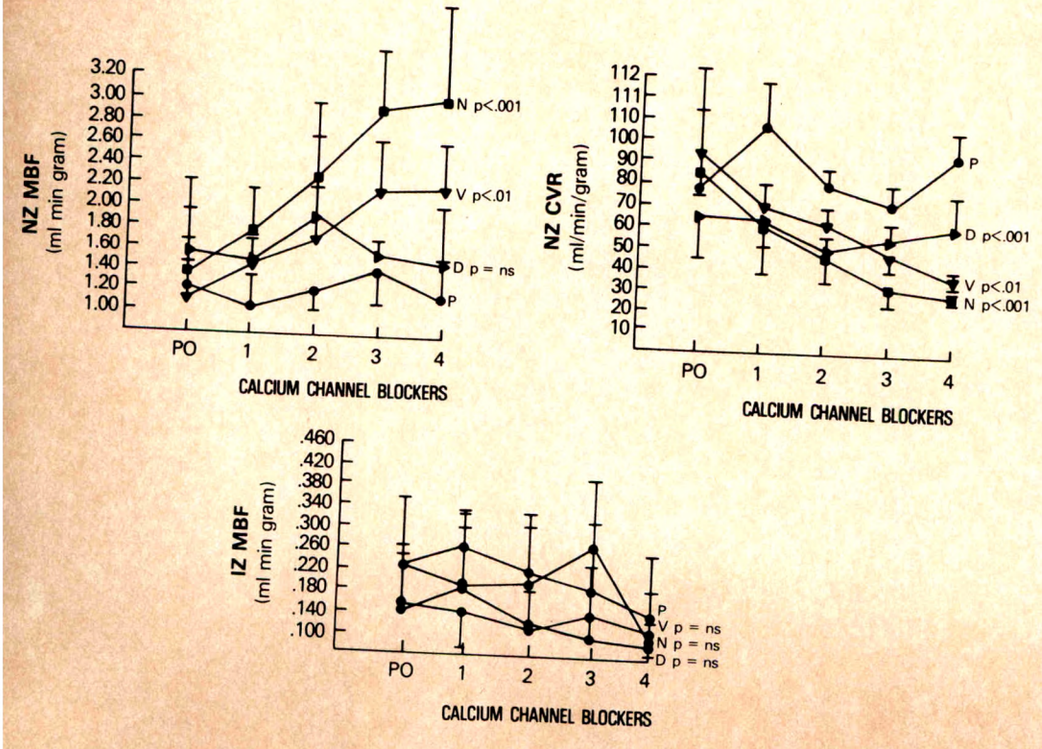

FIGURE 5. Comparison of dose-response curves for myocardial blood flow (MBF) to normal zone (NZ) myocardium and ischemic myocardium (IZ) and coronary vascular resistance (CVR) to NZ myocardium. Reprinted with permission from *Circulation*.[31]

patients with congestive heart failure. Thus Chew et al[43] demonstrated that in patients with severely decreased EF or increased pulmonary capillary wedge pressure, the short-term intravenous administration of verapamil caused further increases in the pulmonary capillary wedge pressure, and led to clinical deterioration.

On the other hand, Walsh et al[44] reported recently that large doses of diltiazem to decrease mean aortic pressure by 20 mm Hg improved LV function in 6 to 8 patients with severe congestive heart failure. It seems crucial, however, to reemphasize their conclusion: that this study of a small number of selected, carefully monitored patients does not establish the safety of calcium-entry blockers in the presence of LV dysfunction. For example, several of their patients had junctional rhythm during the study related to the dose of diltiazem.[44]

To study the influence of heart failure on the hemodynamic effects of the calcium-channel blocking agents, we performed studies in 6 foxhounds undergoing total occlusions of the left anterior descending coronary artery during anesthesia, resulting in myocardial infarction. Two weeks later, while awake, these dogs were volume-loaded to increase left atrial mean pressure to 12 to 15 mm Hg. The circumflex coronary artery was then partially occluded, and left atrial pressure increased to 25 to 30 mm Hg, while left ventricular ejection fraction (LV EF) decreased from 41 to 30%. Verapamil or nifedipine was then administered in graded intravenous doses and LV function was measured by radionuclide angiography. When matching decreases in mean arterial pressure were compared, verapamil depressed global LV EF and raised left atrial pressure to as high as 40 to 45 mm Hg. In contrast, nifedipine decreased left atrial pressure and increased global EF. Thus, verapamil has the potential to cause hemodynamically important deterioration in LV function, particularly in the presence of acute ischemia and LV failure.

While nifedipine has little or no negative inotropic effect when LV function and autonomic reflexes remain intact, hemodynamic compromise may be a problem in patients who are taking β-blocking agents, or who have chronic congestive heart failure; in both situations, cardiac function is compromised and autonomic nervous system adaptations are impaired. In this regard, failure occurring secondary to nifedipine administration has been reported when the drug is given with β-blocking agents,[45] and preliminary reports show that in patients with coexistent LV failure nifedipine has an important negative inotropic effect.[46]

Although the negative inotropic effects produced by verapamil on ischemic tissue can result in frank LV failure, particularly when the zone of ischemia is large, it is possible that the decrease in tension development of ischemic tissue produced by verapamil may actually decrease the degree of ischemia. To evaluate this question, we developed a fiber-optic probe to record intramyocardial pH in the beating heart of an anesthetized open-chest dog.[47] Our studies in dogs[48] that had regional myocardial acidosis after acute coronary occlusion indicate that pretreatment with verapamil reduces the degree of acidosis of ischemic myocardium as it depresses LV function. In contrast, pretreatment with nifedipine caused no change in the degree of acidosis of ischemic myocardium as it increased LV function. These preliminary findings suggest that the negative inotropic effects of verapamil can protect ischemic myocardium, presumably by decreasing its oxygen demand. On the other hand, although nifedipine improves LV function, it does not alter ischemic acidosis.

In conclusion, there are important differences in the hemodynamic effects of the different calcium-entry blocking drugs. First, verapamil appears to have the greatest potential for depressing LV function. Preliminary studies in an animal model of acute ischemia and heart failure show that verapamil may cause serious deterioration of LV function in the setting of congestive heart failure. On the other hand, decreasing contractile function of ischemic myocardium in the nonfailing heart may contribute to reducing ischemic injury by decreasing oxygen demand, and probably contributes importantly to the antianginal potency of verapamil. The negative inotropic effects of verapamil are also accompanied by an improvement in LV diastole function, which also probably contributes to the drug's salutary clinical effects. Diltiazem also depresses LV contractile function, although to a lesser extent than verapamil; thus, LV failure developing in an already decompensated heart after diltiazem administration is a distinct possibility. Nifedipine, on contrast, improves LV function in most patients, presumably by afterload reduction and baroreceptor-induced reflex mechanisms. However, recent reports have shown that nifedipine can cause LV dysfunction in patients with impaired sympathetic function caused by β-blocker therapy, and in patients with LV heart failure. Thus, each of the calcium-channel blockers has a different dose-response relation and different effects on LV systolic and diastolic function. As such, no drug is clearly "better" than any of the others. Rather, this diversity of action enables the physician to tailor therapy to the needs of the individual patient.

Calcium-Entry Blockers, Vascular Smooth Muscle and Systemic Hypertension

PAUL M. VANHOUTTE, MD

Abnormal narrowing of the arterioles, caused by contraction of arteriolar smooth muscle, contributes to the genesis and the maintenance of the increased peripheral resistance observed in hypertension. Activation of the contractile process in vascular smooth muscle requires an increase in cytoplasmic calcium. In most blood vessels, the activator ion enters the cell through specific membrane channels, which can be inhibited by a chemically heterogeneous group of drugs, the calcium-entry blockers. The antihypertensive effect of these agents is probably explained by their inhibitory effect on (1) α-adrenergic activation (the pharmacologic subtype of postjunctional α-adrenoceptor does not necessarily determine the importance of calcium entry); (2) activation by nonadrenergic neurohumoral mediators (for example, serotonin); (3) acceleration of calcium entry by metabolites of arachidonic acid formed by lipoxygenase; and (4) inherent myogenic tone. **(Am J Cardiol 1985;55:17B–23B)**

In most patients with borderline or chronic hypertension, the cardiac output and the viscosity of blood are normal; the increase in arterial blood pressure is due to an augmented systemic vascular resistance. Thus, chronic arterial hypertension is now viewed as caused by the abnormal narrowing of the systemic resistance vessels.[1,2]

Vascular Responsiveness in Essential Hypertension

No single derangement is responsible for the increased systemic vascular resistance in essential hypertension (Fig. 1). Because the onset of hypertension is symptomless, the initiating factors may be obscured at the time it is detected by adaptations secondary to the long-term increase in arterial blood pressure.

In the early stages of hypertension, it seems likely that an exaggerated release of norepinephrine (NE) in the blood vessel wall contributes to increased arterial blood pressure. This conclusion is strengthened by the observations that removal of the sympathetic nervous system prevents the occurrence of hypertension in most animal models of the disease. Several factors may participate in the augmented sympathetic outflow to the vascular periphery, including abnormal activity of the higher nervous centers under the influence of stress or because of an augmented production of angiotensin II acting directly on the brain;[3] resetting of the mechanoreceptors governing the homeostatic control of blood pressure;[4] and greater than normal release of NE by the adrenergic nerve endings.[5,6] The latter can be due to inherent defects in the adrenergic neurons or to presence of neurohumoral mediators that facilitate the release or delay the disposition of the adrenergic transmitter, as could be the case for angiotensin II or circulating inhibitor(s) of Na^+, K^+ ATPase.[5–7]

The responsiveness of the vascular smooth muscle to the incoming sympathetic impulses can be modulated on both a short- and long-term basis. Among the circulating neurohumoral substances that can amplify vascular responsiveness to NE are angiotensin II and 5-hydroxytryptamine (serotonin).[8] To judge from experiments performed in animal blood vessels with cardiac glycosides, circulating inhibitor(s) of Na^+,K^+ ATPase would mainly prolong the effect of released NE and slow down the dilatation occurring upon cessation of sympathetic nerve activity.[7] Of the long-term important factors, structural adjustments of wall thickness, whether caused by water logging or proliferation of smooth muscle or both, probably play the major role. However, true hypersensitivity to vasoconstrictor agents, in particular NE, may also occur.[2,6] One of the consequences of long-term exposure of the blood vessel wall to increased pressure may be its premature aging, with a characteristic augmentation of the responsiveness to the contractile effect of serotonin.[9]

Calcium Entry and Vascular Smooth Muscle

Activation of the contractile process in vascular smooth muscle cells depends on the phosphorylation of myosin after activation of the myosin light chain kinase by the calmodulin-calcium complex. Thus, the cytoplasmic concentration of calcium is critical in determining the degree of interaction between actin and myosin, and hence the contractile state of the smooth muscle.[10–14] The cytoplasmic concentration of calcium is the result of a number of cellular processes with opposing effects (Fig. 2).

Increases in calcium concentrations can be brought about either by mobilization from cellular stores (for example, internal surface of the cell membrane, sarcoplasmic reticulum) or by increasing the permeability of the cell membrane. The latter is thought to be the consequence of the opening of specific channels (calcium channels) within the cell membrane. The opening of these channels can be induced either by changes in membrane potential (potential-operated channels), by binding of neurohumoral mediators to specific receptors of the cell membrane (receptor-operated channels) or by binding to a receptor followed by cell membrane depolarization. Cellular mobilization of calcium can be triggered by neurohumoral mediators in the absence of calcium entry.[15–21]

Decreases in cytoplasmic calcium concentrations follow the activation of active pumps such as Na^+,K^+ ATPase, Ca^{++} ATPase or Na^+,Ca^{++} exchange systems. These processes will relocate the ion into the cellular storage sites or move it to the extracellular space. The removal of calcium from the cytoplasm is accelerated by the production of cyclic nucleotides, in particular cyclic adenosine monophosphate, the hyperpolarization of the cell membrane or both.[1,10,12,22]

Calcium-Entry Blockers and Vascular Responsiveness: Vasoconstrictor Agents

Norepinephrine: The NE liberated by sympathetic nerve endings binds to postjunctional (postsynaptic) α-adrenoceptors, which in turn activate the contractile process. Depending on their affinity for a variety of agonists and antagonists, alpha-adrenoceptors can be subdivided into at least 2 subtypes (α_1- and α_2-adrenoceptors) (Fig. 3). The postjunctional α-adrenoceptors can belong to both subtypes.[23–25] This has been demonstrated in particular in intact animals and man, but can also be evidenced in isolated blood vessels.[26] The relative importance of the α_1- versus α_2-adrenergic component of the postjunctional action of catecholamines may vary, because it can be modulated by circulating substances or by local physical conditions. For example, angiotensin II[27] and inhibitors of Na^+ K^+ ATPase[7] may favor α_2-adrenergic activation. Local warming augments the responsiveness to α_1-adrenergic agonists but reduces α_2-adrenergically mediated responses.[28]

A remarkable feature of the response of vascular smooth muscle to NE is the heterogeneity among blood vessels from the same or different species concerning the dependence of α-adrenergic activation and the entry of extracellular calcium. As a consequence, the calcium-entry blockers can vary widely in their ability to inhibit NE-induced contractions in various blood vessels.[16,17,21,23,29–39] For example, in the canine saphenous vein, calcium-entry blockers only moderately depress the contractile response to exogenous norepinephrine (Fig. 4), phenylephrine or sympathetic nerve stimulation. The canine femoral and coronary arteries (Fig. 5) and the rabbit aorta are much more susceptible to inhibition of calcium-entry during α-adrenergic activa-

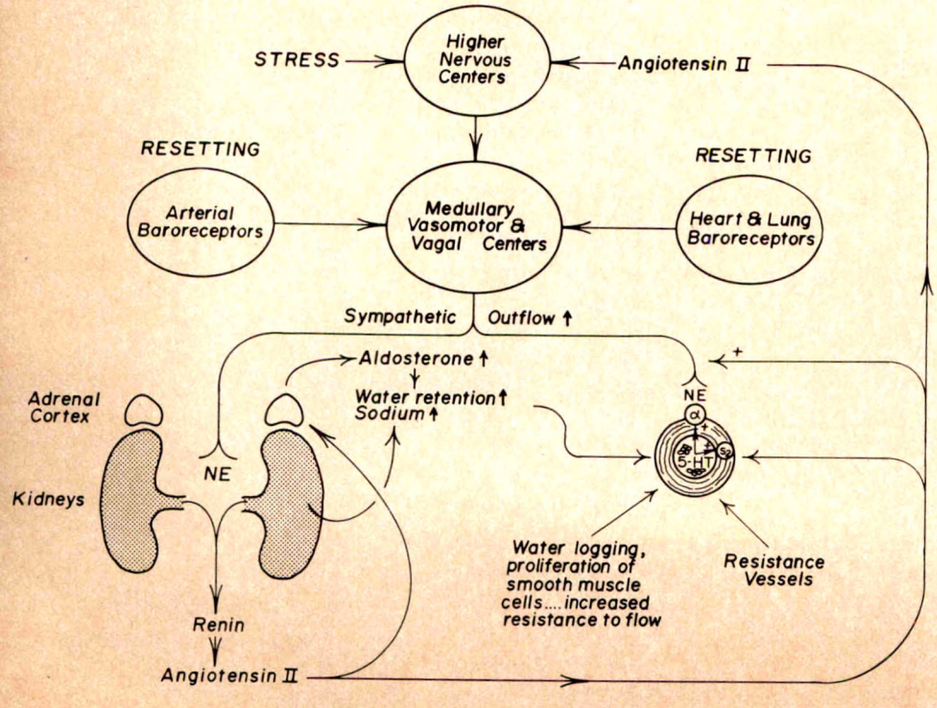

FIGURE 1. Factors that may be involved in genesis of increased peripheral resistance in essential hypertension. In many instances, sympathetic outflow is increased, particularly in early stages of the disease. In addition, for each level of sympathetic nerve activity, adrenergic nerve terminals may liberate more NE than normal and α-adrenoceptors of vascular smooth muscle cells may be more sensitive to transmitter. Possible interference of serotonin is shown either as direct effect on S_2-serotonergic receptors mediating contraction of vascular smooth muscle cells, or as amplifying effect (also mediated by S_2-serotonergic receptors) on response of vascular smooth muscle cells to other vasoconstrictor stimuli. For clarity, only α-adrenergic activation is mentioned. 5-HT = serotonin; NE = norepinephrine; ↑ = increase; and + = facilitation. Reprinted with permission from Butterworths.[2]

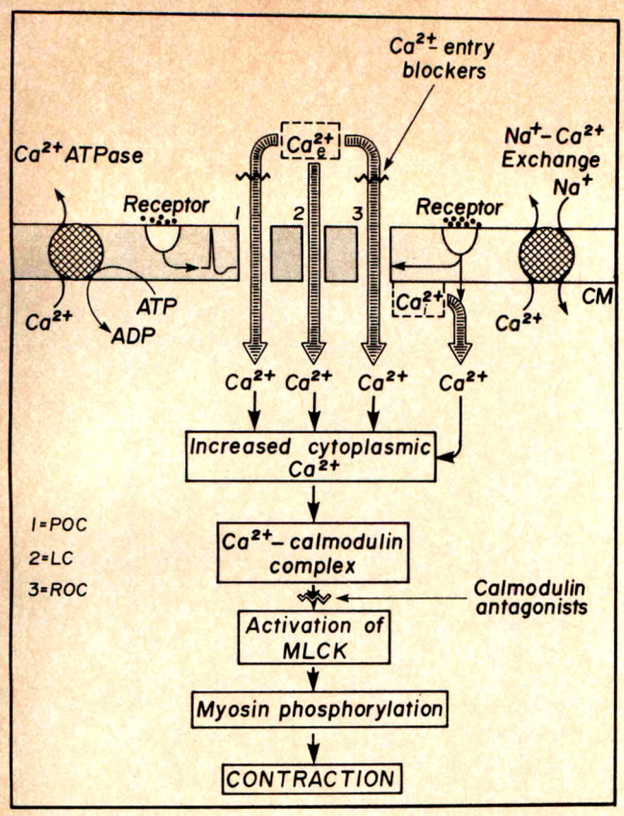

FIGURE 2. Calcium-dependent regulation of contractile activity in vascular smooth muscle. Cytoplasmic calcium (Ca^{++}) levels are increased by calcium influx through cell membrane (CM) potential-operated calcium channels (1 = POC), passive calcium "leak" pathway (2 = LC) (calcium entry that occurs under resting conditions) and receptor-operated calcium channels (3 = ROC). Receptor occupation by specific agonist (**closed circles**) may also induce release of calcium from intracellular storage sites or may depolarize cell membrane and activate potential operated channel. Calcium activates myosin light chain kinase (MLCK) by binding to calmodulin. Activated MLCK catalyzes phosphorylation of myosin, which increases actin-myosin interactions resulting in contraction. Cytoplasmic calcium levels are reduced through operation of cell membrane pumps, including Ca^{++}-ATPase (**far left**) and Na^{+}/Ca^{++} counter-transport (**far right**) that promote calcium efflux. **Closed wavy lines,** inhibited by calcium-entry blockers; **open wavy lines,** inhibited by hydrophobic compounds including pimozide and trifluoperazine. tion. It is uncertain why calcium-entry blockers differentially affect the response of various blood vessels to alpha-adrenoceptor stimulation. One explanation is that the smooth muscle cells contain different proportions of postjunctional α_1- and α_2-adrenoceptors, which could be linked preferentially to either the entry of extracellular calcium or the mobilization of intracellular stores of the ion.[23,33] Thus, in canine arteries and in rabbit aorta, the postjunctional α-adrenoceptors are characterized as α_1 and appear to be linked preferentially to calcium entry (Fig. 5). However, in the isolated canine saphenous vein and in resistance vessels of pithed animals, certain postjunctional α-adrenoceptors possess characteristics of the α_2 subtype, and when activated also trigger the entry of extracellular calcium (Fig. 6). Thus, the varying degrees of the dependence of the response to NE upon calcium entry are not determined by the pharmacologic characteristics (α_1 or α_2) of the postjunctional adrenoceptors involved, but rather by the functional differentiation of the vascular smooth muscle.[23,32,34]

Nonadrenergic activation: Calcium-entry blockers inhibit constrictions of arteries, in particular cerebral

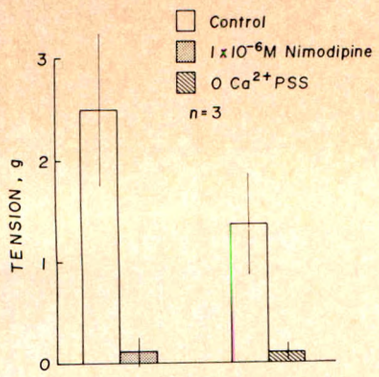
and coronary arteries, caused by vasoconstrictor substances such as serotonin, ergonovine maleate (Fig. 7) and prostaglandin $F_{2\alpha}$.[16,17,21,23,29,30] In cutaneous veins, calcium-entry blockers that have little or no effect on the response to NE markedly inhibit the response to acetylcholine (Fig. 4). This demonstrates that in certain blood vessels, depending upon the cell membrane receptor involved, the activation of the contractile process relies to a varying degree upon the entry of extracellular Ca^{++}.

Ca^{++} Entry and Metabolism of Arachidonic Acid

Contractions of canine saphenous veins evoked by acetylcholine are augmented by inhibitors of cyclo-oxygenase; this augmentation is not observed in the presence of inhibitors of lipoxygenase and is inhibited by the calcium-entry blockers diltiazem and nimodipine.[40] Hypoxia augments the contractions of canine saphenous veins evoked by acetylcholine and this augmentation is blocked by calcium-entry blockers.[41] Contractions also occur in quiescent coronary arteries exposed to hypoxia,[42] in the same preparation, hypoxia greatly augments contractions evoked by NE and serotonin.[43] The hypoxic contractions of coronary smooth muscle are prevented by calcium-entry blockers (Fig. 8) and by inhibitors of lipoxygenase. These findings suggest that metabolites of arachidonic acid can modulate calcium entry.[40,42,44] Activation of cell membrane receptors or cell membrane depolarization accelerates the entry of calcium, which in turn triggers the contraction (Fig. 2). Calcium entry into the cell also activates phospholipase, and production of arachidonic acid results. Under normal conditions, arachidonic acid is metabolized through cyclo-oxygenase to prostanoids, which have varying effects on smooth muscle tone depending on the blood vessel considered. However, if cyclo-oxygenase is inhibited, either pharmacologically



IGURE 8. Effect of nimodipine (**left**) and calcium removal (**right,** 0 Ca^{++} SS) on hypoxia-induced contractions in canine coronary artery. or by tissue hypoxia, arachidonic acid is diverted through the lipoxygenase pathway. The end products of the action of this enzyme then in turn (and in an unknown way) greatly accelerate calcium entry, and thus favor contraction of the smooth muscle (Fig. 9).

Myogenic Tone

The arterioles are characterized by their propensity to develop myogenic tone; this phenomenon depends highly upon the influx of extracellular calcium. In certain isolated blood vessels, most notably portal-mesenteric veins of different species (Fig. 10 and 11), spontaneous rhythmic (myogenic) contractions that depend on availability of extracellular calcium can also be observed.[1,31] They presumably result from spontaneous depolarization of the cell membrane, which then opens calcium channels (Fig. 8). The degree of myogenic activity is dependent on the distension imposed upon the blood vessel wall (Fig. 10), in part because progressive distension causes depolarization of the cell membrane, bringing it closer to threshold for spontaneous action potentials. This relation helps to explain the maintenance of blood flow despite variations of arterial blood pressure (autoregulation).[1] This may be of particular importance in those cases of hypertension in which total body autoregulation contributes to the genesis of the disease.

Calcium-entry blockers inhibit the myogenic activity of portal-mesenteric veins with varying potencies, with the dihydropyridines (for example, nifedipine) being the most potent (Fig. 11).[16,17,29,44,45] Because the myogenic tone of the arterioles also depends upon the entry of extracellular calcium, it is not surprising that the calcium-entry blockers, which are the most potent inhibitors of spontaneous activity in portal-mesenteric veins, also cause the greatest decrease in peripheral vascular resistance in the intact organism, and hence are the most likely candidates as antihypertensive agents.

In summary, a number of chemically distinct pharmacologic agents, including cinnarizine, diltiazem, flunarizine, lidoflazine, methoxyverapamil, nifedipine and verapamil, can antagonize the entry of calcium during activation of vascular smooth muscle cells. However, because the source of calcium (entry or cellular mobilization) varies, depending on the anatomic origin of the vascular smooth muscle and the means by which it is activated, the effect of the calcium-entry blockers in antagonizing the contractile responses of isolated blood vessels may vary considerably. In large blood vessels, the main controller of vascular diameter is the sympathetic nervous system. The NE liberated by the adrenergic nerve endings binds to postjunctional alpha-adrenoceptors, which activate the contractile process. In certain arteries and veins, calcium-entry blockers only moderately depress the contractile response to exogenous NE or sympathetic nerve stimu-

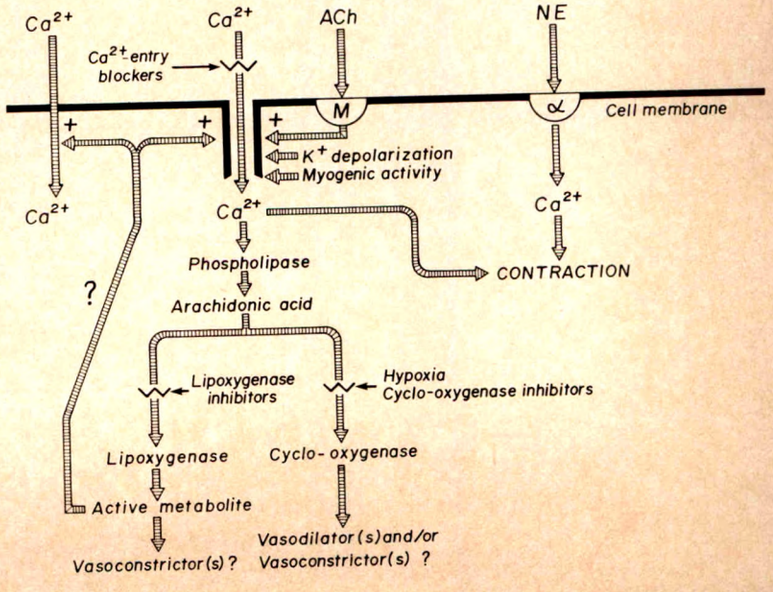

FIGURE 9. Proposed interaction between calcium entry and arachidonic acid metabolism in canine vascular smooth muscle. In saphenous vein, contractions induced by acetylcholine (ACh) and potassium (K^+) are inhibited by calcium-entry blockers, but potentiated by inhibitors of cyclo-oxygenase. Contractions induced by norepinephrine (NE) are only moderately reduced by calcium-entry blockers and are not augmented by inhibitors of cyclo-oxygenase. In coronary artery, hypoxia inhibits cyclo-oxygenase and induces a contraction that can be inhibited by calcium-entry blockers. Augmentation of entry of calcium by ACh, K^+ and hypoxia results in activation of phospholipase. Proposed arachidonic acid is diverted into lipoxygenase pathway (when cyclo-oxygenase is inhibited pharmacologically or by hypoxia), products of which in an unknown fashion enhance entry of calcium through calcium channel or possibly by acting as calcium ionophore. α = alpha-adrenoceptor; Ca^{++} = calcium; M = muscarinic receptor; + = augmentation; ? = unknown; wavy lines = inhibition. Reprinted with permission from Martinus-Nijhoff.[42]

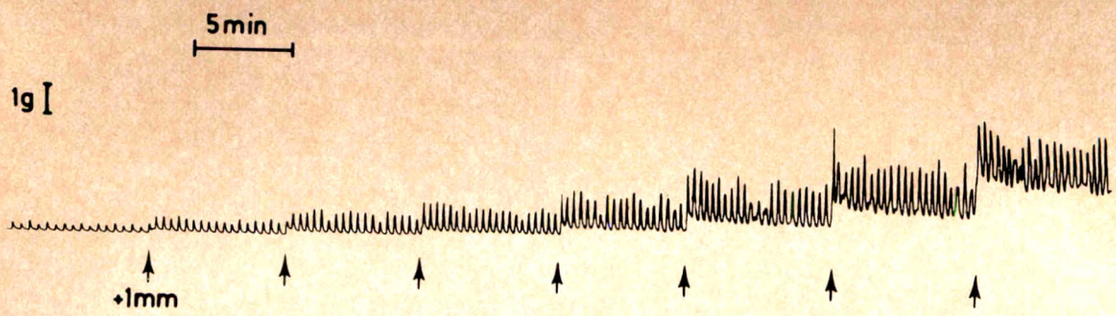

FIGURE 10. Progressive distension augments rate and amplitude of spontaneous contractions in canine portal-mesenteric vein. Reprinted with permission from W. B. Saunders.[31]

lation, indicating that in these smooth muscles catecholamines activate the contractile process mainly by enhanced cellular mobilization of calcium. However, most veins and arteries, including the coronaries, are very sensitive to inhibition of calcium entry during α-adrenergic activation. The reason for the differential effects of calcium-entry blockers on the response of various isolated blood vessels to α-adrenergic activation is still uncertain. Calcium-entry blockers inhibit contractions of most isolated arteries caused by nonadrenergic vasoconstrictor substances, such as serotonin, ergonovine maleate and prostaglandin $F_{2\alpha}$. In certain blood vessels, most notably the precapillary resistance vessels, the portal-mesenteric vein of different species and the human coronary artery, spontaneous activity is observed under control conditions. This myogenic activity depends on the availability of extracellular calcium and is presumably caused by spontaneous depolarization of the cell membrane, which then opens specific potential-operated calcium channels. Most calcium-entry blockers inhibit myogenic activity of vascular smooth muscle. However, the potency of the available compounds varies in this regard, with the dihydropyridines being the most potent. Because myogenic tone of the arterioles also depends upon the entry of extracellular calcium, it is not surprising that the calcium-entry blockers, which are most potent in inhibiting the spontaneous activity of portal-mesenteric veins, appear to cause the greatest decrease in peripheral vascular resistance in the intact organism, and hence are the most likely candidates for antihypertensive agents.

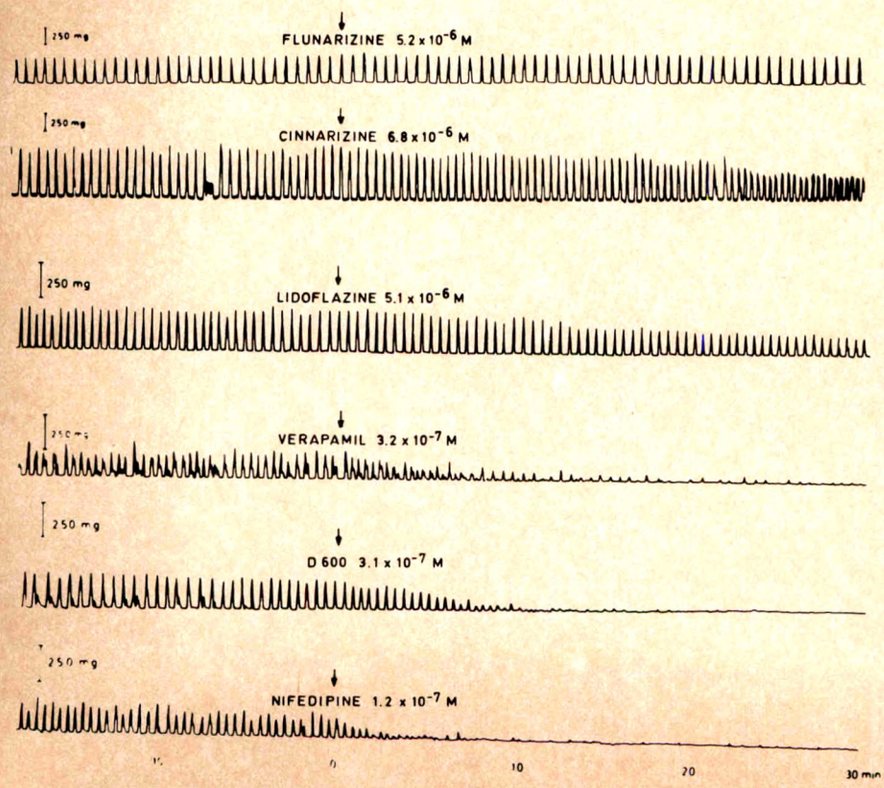

FIGURE 11. Experiments on isolated portal-mesenteric veins of rat. Inhibitory effect of flunarizine, cinnarizine, lidoflazine, verapamil, methoxyverapamil (D 600) and nifedipine on myogenic activity were studied at concentration producing 80 to 100% inhibition of response to Ca^{++} in rat caudal artery preparation. Functional Differences in Blood Vessels Determined from Studies with Calcium-Channel Blockers

Functional Changes in Forearm Resistance Vessels of Men With Primary Hypertension

BRIAN F. ROBINSON, MD

Vascular smooth muscle is activated through 2 major systems. One, which can be inhibited by calcium-entry blocking agents, involves the influx of calcium through potential-sensitive channels. The other, which can be inhibited by sodium nitroprusside, involves the entry of calcium through agonist-controlled channels and probably its mobilization from within the cell as well. Human veins, muscular arteries and resistance vessels show differing patterns of response to agents that selectively inhibit the 2 activation systems. The responses indicate that physiologic contractions of cutaneous veins and muscular arteries depend on the agonist-controlled system; contractions of veins induced by high concentrations of potassium depend on the potential-sensitive system as, probably, does local spasm in arteries. The tone of resistance vessels depends on a balance between the potential-sensitive and agonist-controlled systems. The forearm resistance vessels of men with primary hypertension respond to verapamil with larger-than-normal dilatation compared with that induced by nitroprusside. This is interpreted as showing an increased contribution to resistance vessel tone from the potential-sensitive system. This functional abnormality does not depend on the inhibition of sodium pump activity that is known to occur in hypertension, because it cannot be reproduced by local infusion of ouabain. It probably results from a primary disorder of calcium handling by the cell membrane.

(Am J Cardiol 1985;55:24B–29B)

Different types of blood vessels play widely differing roles in circulatory control and it is not surprising that vascular smooth muscle, unlike skeletal or cardiac muscle, shows considerable functional diversity. The varying modes of contractile behavior that it exhibits are associated with a range of mechanisms whereby the concentration of free calcium in the cytosol can be increased and activation of the contractile mechanism achieved. The activation systems are complex and the details of their operation far from clear. This article presents an oversimplified but nonetheless useful framework within which to consider the functional behavior of blood vessels.

Activation Systems in Vascular Smooth Muscle

There appear to be 2 major systems by which activation of vascular smooth muscle can be achieved.[1] The first involves entry of calcium through potential-sensitive channels in the cell membrane that are analogous to the slow-calcium channels in myocardial cells. This activation system is controlled by membrane potential, but can be modulated by agonists such as noradrenaline. The potential-sensitive channels are selectively inhibited by calcium-entry blockers such as verapamil and nifedipine. The second system is less clearly defined; it appears to involve calcium entry through membrane channels that are agonist-controlled and probably involves release of calcium from intracellular stores. The second system, or group of systems, is relatively insensitive to verapamil and even less sensitive to nifedipine. It is selectively inhibited by sodium nitroprusside and organic nitrates.

The potential-sensitive system is typically involved in spontaneous phasic activity as in the rhythmic contractions of the rat portal vein; such activity is associated with bursts of action potentials that may be triggered by slow oscillations of the membrane potential.[2] The potential-sensitive system also mediates the sustained contractions that develop when the membrane is depolarized by exposure to high concentrations of extracellular potassium.

The agonist-controlled system is typically involved in sustained contractions induced by agents such as noradrenaline; it mediates the tonic contractions of cutaneous veins that result from sympathetic nerve activity. It is also involved in sustained contractions of large arteries whether induced in vivo by sympathetic nerve activity or in vitro by noradrenaline.

Methods for Investigation of Human Blood Vessels

We examined responses to vasoactive agents in 3 different types of blood vessels: the forearm resistance vessels, dorsal hand veins and small collateral arteries that course around the elbow. The response of the forearm vascular bed is dominated by that of the resistance vessels in skeletal muscle: the forearm resistance vessels were assessed by local infusion of drugs into the brachial artery on 1 side and measurement of changes in blood flow by venous occlusion plethysmography using mercury-in-silastic strain gauges. Dorsal hand veins serve as a model for superficial limb veins and their response mirrors that of the systemic venous reservoir as a whole. Drugs are infused locally into a single hand vein, which is congested to a pressure of about 15 mm Hg by a cuff on the upper arm. Changes in vein size are detected by a simple displacement transducer that rests on the vessel about 1 cm below the infusion point.[3] Vessels such as the ulnar collateral, which connect the distal segment of the brachial artery to the proximal parts of the radial and ulnar arteries, serve as models of small muscular arteries. Their responses are assessed by estimating their resistance to blood flow during temporary occlusion of the brachial artery. Resistance is derived from simultaneous measurement of the forearm blood flow and the pressure difference that develops between the brachial and forearm arteries during arterial occlusion. Collateral arterial resistance is measured before and after systemic administration of drugs.[4]

The comparative effectiveness of dilator agents in forearm resistance vessels and dorsal hand veins is assessed by determining the relative potencies of 2 or more drugs, first in 1 type of vessel and then in the other. In the forearm resistance vessels, for example, sodium nitroprusside induces dilatation at about one-tenth the dose required for verapamil; in the hand veins, however, nitroprusside is effective at about one-thousandth the dose of verapamil (Fig. 1). Because blood flow in the brachial artery is likely to be at least 20 times greater than that in a single hand vein, it can be inferred from the dose-response curves that veins are probably somewhat less sensitive to verapamil than resistance vessels; they are, however, much more sensitive to nitroprusside. From such studies, it has been possible to determine the differential responsiveness of resistance vessels and veins to several vasoactive agents; some of these findings are summarized in Table I.

Many dilator drugs act preferentially on blood vessels of 1 type, but the reasons for this selectivity vary. The venoselectivity of the α_1 adrenoceptor antagonist, prazosin, reflects the fact that cutaneous veins depend entirely on sympathetic stimulation for maintenance of contraction; in contrast, resistance vessels possess intrinsic tone and do not relax completely when noradrenergic activity is inhibited. Differential responses to other drugs may reflect differences in innervation or receptors, differences in responsiveness to metabolites and differences in the contribution of mediators arising in the intima. For drugs such as verapamil and nitroprusside, however, differences in response depend on the varying importance of the potential-sensitive and agonist-controlled systems in activating the vascular smooth muscle. From studies of the effects of drugs in

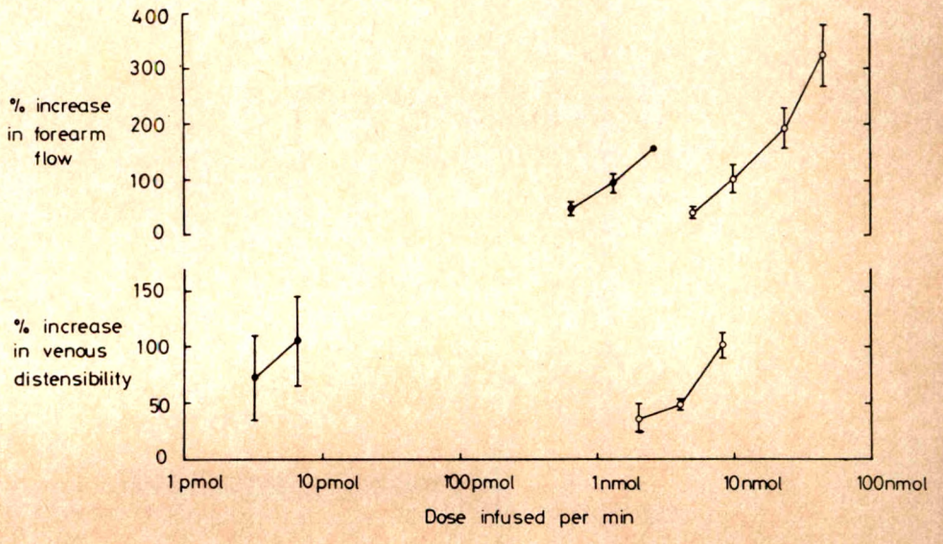

FIGURE 1. Effect of verapamil (**open circles**) and sodium nitroprusside (**closed circles**) on forearm blood flow and distensibility of noradrenaline-constricted hand vein. Mean and standard error of the mean are shown. Dose ratio in forearm is about 10:1; in vein it is 1,000:1. Reprinted with permission from *Cardiovasc Res.*[6]

TABLE I Comparative Effectiveness of Dilator Agents in Blood Vessels of Different Types in Man

Drug	Mechanism of Action	Cutaneous Veins		Muscular Arteries	Resistance Vessels
		Noradrenaline-Contracted	High K^+-Contracted		
Nifedipine	Inhibit calcium entry	0	++	0	++
Verapamil	through potential-sensitive channels	+	++	?	++
Glyceryl trinitrate	Inhibit other systems for calcium entry or release	++	+	++	+
Sodium nitroprusside		++	?	?	+
β-agonists	β adrenoceptor linked-cAMP generation	+	?	+	++
Prazosin	α_1-adrenoceptor antagonist	++	0	?	+
Hydralazine	Not known	0	0	?+	++
Diazoxide	Not known; ? acts on common mechanism at late stage of activation process	+	?	?	+

cAMP = adenosine 3′:5′-cyclic monophosphate; K^+ = potassium; + = sensitive; ++ very sensitive.

these groups, it has been possible to learn something of the functional differences between blood vessels of different types.

Functional Characteristics of Human Blood Vessels

The independent operation of the potential-sensitive and agonist-controlled systems for activation of smooth muscle can be most clearly observed in the behavior of the dorsal hand veins in man. Physiologic contractions of these vessels, as with other large subcutaneous veins, are normally dependent on stimulation by the sympathetic nerves that supply them. Sustained contractions that mimic those occurring physiologically can be induced by local infusion of noradrenaline in the range of 4 to 32 ng/min. Noradrenaline-induced contractions of this type can be inhibited by low concentrations of sodium nitroprusside, which is consistent with their being mediated by the agonist-controlled system.[5] As would be expected, they are relatively insensitive to verapamil[6] and resistant to nifedipine at concentrations up to 100 times the threshold for relaxation of the resistance vessels.[7] As the noradrenaline-contracted vein is relaxed by nitroprusside, however, small-amplitude phasic contractions with a frequency of 5 to 6 per minute are often seen (Fig. 2). These nitroprusside-resistant contractions are inhibited by relatively low concentrations of verapamil,[6] which is consistent with activation by the potential-sensitive system.

The differential effect of nifedipine on sustained contractions of hand veins evoked by local infusion of noradrenaline and potassium, respectively, provides a particularly clear illustration of the 2 basic modes of activation. Hand vein contractions induced by noradrenaline are unaffected by local infusion of nifedipine in doses up to 3.2 μg/min. When contractions of similar magnitude are produced by local infusion of potassium (K^+), 100 mmol/liter (together with phentolamine to block the effect of released noradrenaline), they can be inhibited by infusion of nifedipine in the range of 100 to 400 ng/min.[7] The noradrenaline-induced contraction depends on the agonist-controlled system; the appar-

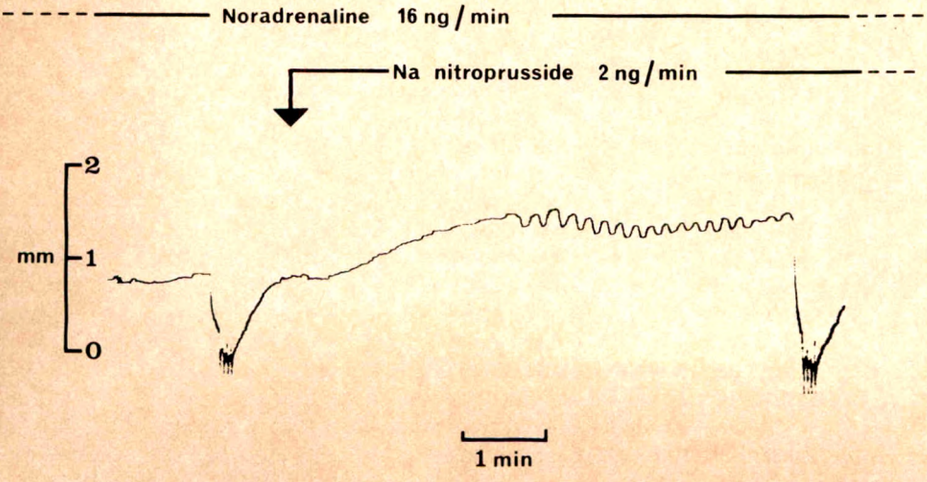

FIGURE 2. Response of noradrenaline-constricted hand vein to sodium nitroprusside: continuous recording of size of single dorsal hand vein maintained at constant pressure by cuff on upper arm inflated to 25 mm Hg. Cuff was deflated on 2 occasions and vein allowed to collapse to establish baseline. Vein was preconstricted by local infusion of noradrenaline at 16 ng/min. Infusion of sodium nitroprusside at 2 ng/min induces relaxation of sustained contraction, but leads to appearance of small-amplitude phasic contractions. Reprinted with permission from *Br J Clin Pharmacol.*[5]

ently similar contraction induced by high concentrations of K^+ results from depolarization with activation of the potential-sensitive system.

Varying patterns of smooth muscle activation may be observed in vessels of other types. Small arteries appear, in general, to behave in a way similar to cutaneous veins with physiologic tone depending on the agonist-controlled system. In accordance with this pattern, the collateral arteries that normally course around the elbow in man were found to decrease their resistance by about half after sublingual administration of glyceryl trinitrate (0.5 mg)[4], but showed no decrease in resistance after 10 mg of sublingual nifedipine.[7] The large coronary arteries may have a slightly different pattern of activation: they dilate readily to both glyceryl trinitrate and nitroprusside.[8] However, some vessels also show partial relaxation in response to intravenous verapamil[9] and a minority were found to dilate weakly in response to sublingual nifedipine.[10] It is interesting to note that localized spasm of coronary arteries is typically very sensitive to nifedipine;[11] this suggests that the pathologic mode of contraction involved in spasm depends on the potential-sensitive system and presumably depends on local depolarization of the vascular smooth muscle. The observation that organic nitrates may also be effective in relieving spasm is not inconsistent with this view because the nitrates can induce partial relaxation of K^+-induced contractions.[12]

Little is known of the behavior of the portal and splanchnic veins in man. In several animal species, however, the portal vein exhibits strong phasic contractions that are selectively inhibited by calcium-entry blockers.[1]

The control of resistance vessels is more complex than in the larger vessels and the relative importance of the 2 basic modes of activation almost certainly differs from bed to bed. In resistance vessels of the human forearm, both potential-sensitive and agonist-controlled systems contribute to the maintenance of tone; neither verapamil nor sodium nitroprusside can induce full dilatation, even at maximally effective doses.[13] These characteristics probably reflect the behavior of the skeletal muscle bed; blood flow in the fingertip skin does not increase in response to verapamil.[14]

Functional Changes in Resistance Vessels in Primary Hypertension

In light of the understanding of vascular smooth muscle function gained by studying the effect of dilator agents in normal blood vessels, it appeared that it should be possible to use drugs of this type to investigate functional changes occurring in circulatory disorders. The relative effectiveness of a calcium-entry blocking drug and of sodium nitroprusside in inducing dilatation of the same resistance bed should provide an indication of the relative importance of the 2 activation systems in maintaining vascular tone. We decided to use this approach to investigate the functional behavior of forearm resistance vessels in patients with hypertension.

A functional disorder in the resistance vessels has long been considered as a possible mechanism by which an increase in arterial pressure might be initiated and maintained. Several studies demonstrated an enhanced response to noradrenaline,[15–17] but it has been pointed out that this could result entirely from structural changes in the vessels and need not imply any functional change in the vascular smooth muscle.[18] It is known that long-term increase of arterial pressure leads to medial hypertrophy with an increase in the wall lumen ratio in the arterioles.[19] It has been reasoned from this that as the smooth muscle of the media contracts, the thickened media will encroach on the lumen. The result is that for any given fractional shortening of the myocytes, a greater-than-normal increase in vascular resistance occurs. Thus it has been proposed that the effects of both constrictor and dilator agents on vascular resistance may be enhanced in patients with hypertension purely as a result of structural changes in the vessels.[18] Any attempt to demonstrate a functional abnormality in the resistance vessels must overcome this argument.

An initial study of the effect of dilator agents on forearm resistance vessels was carried out in 35 men with primary hypertension and 23 men with normal arterial pressures of similar age range.[20] Forearm blood flow was measured by venous occlusion plethysmography with mercury-in-silastic gauges. Drugs were infused into the brachial artery on 1 side and dose-response curves were obtained to increasing doses, first of verapamil and then, after an appropriate interval, sodium nitroprusside. The patients had a significant enhancement of the dilator response to verapamil; their response to nitroprusside, however, tended to be less than that of the normal control subjects. When the response to verapamil was compared with the response to nitroprusside in the same subjects, the patients had a highly significant enhancement of the response to verapamil relative to nitroprusside (Fig. 3). A similar increase in responsiveness to verapamil was reported from Switzerland.[13] The difference in response to the 2 dilators cannot be explained by structural changes in the vessels because if these had influenced the decrease in resistance that was achieved, they would have increased the response to both drugs to a similar extent. As with other nonspecific influences, the effect would have been to shift response to the upper part of the normal regression line (Fig. 3). The alteration in responsiveness must therefore reflect a functional disorder. We believe these findings show that the potential-sensitive system makes a proportionally greater contribution to the maintenance of resistance vessel tone in patients with hypertension than in normal subjects. This agrees with the view that the increase in vascular resistance results from a selective increase in the intrinsic, or myogenic, component of arteriolar tone because this is believed to depend on the entry of calcium through potential-sensitive channels.

There is evidence of impaired sodium pump activity in the leukocytes of patients with hypertension and it is believed that this results from the presence of circulating inhibitor in plasma.[21] It has been proposed that

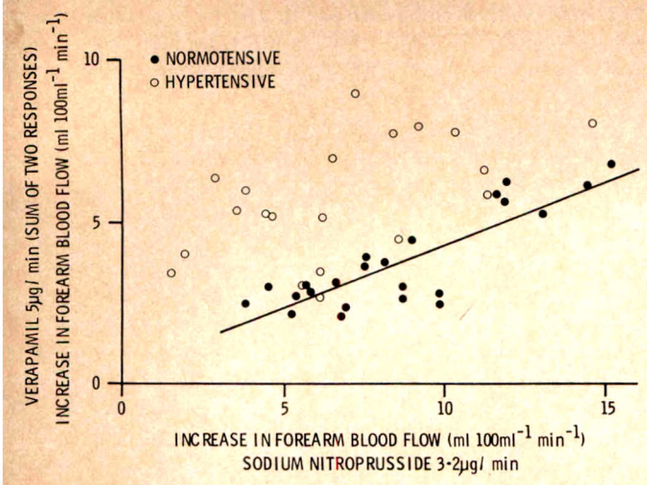

FIGURE 3. Increase in forearm blood flow in response to sodium nitroprusside (3.2 μg/min) related to sum of responses to 2 infusions of verapamil (5 μg/min). Responses to 2 drugs vary widely in normotensive subjects (**closed circles**), but show close linear correlation ($r = 0.85$, $p < 0.01$); this indicates that variability results from nonspecific factors that influence response to both dilators. Most patients with hypertension (**open circles**) have responses to verapamil that exceed those expected from response to nitroprusside. Reprinted with permission from *Clin Sci.*[20]

pump activity is also depressed in the smooth muscle of the resistance vessels with a consequent increase in intracellular sodium. It has been further proposed that increased intracellular sodium reduces the effectiveness of a sodium/calcium exchange mechanism, and so leads to an increase in cytosolic calcium with a resultant increase in resistance vessel tone[22,23] We therefore attempted to determine if the enhanced responsiveness to verapamil in patients with hypertension was a consequence of decreased sodium pump activity. Ouabain was infused into the brachial artery of normal subjects at 2 μg/min for 1 hour. This procedure impaired the dilator response to small increments in plasma K^+ concentration, indicating that significant inhibition of sodium pump activity had been achieved, but it had no effect on the response to verapamil or nitroprusside.[24] We concluded that the enhanced activity of the potential-sensitive activation system did not result from decreased activity of the sodium pump.

In more recent studies, it has been shown that responsiveness to verapamil can be selectively altered by small changes in plasma calcium concentration. Infusion of calcium into the brachial artery at a rate sufficient to increase the plasma concentration by about 0.5 mmol/liter depresses the response to verapamil in both normal subjects and patients with hypertension.[25,26] After discontinuing calcium infusion, responsiveness to verapamil increases in the resistance vessels of normal subjects so that their pattern of response now resembles that of patients with hypertension.[25] It thus appears that the activity of the potential-sensitive system can be modulated by calcium itself. Depression of activity during calcium infusion is probably mediated by an increase in calcium binding to the membrane. The increase in activity when the infusion is discontinued must reflect the induction of some long-lasting change in the physico-chemical characteristics of the membrane, but the nature and mechanism of this transformation are unknown.

A growing body of evidence points to an underlying abnormality in the way in which calcium is handled by cell membranes in hypertension: adenosine triphosphate-dependent calcium transport is impaired in membrane preparations derived from vascular smooth muscle of the spontaneously hypertensive rat,[27,28] and calcium binding appears defective in erythrocytes from both the rat[29] and patients with primary hypertension.[30] Calcium plays an important role in regulating membrane function that is distinct from its direct role in activating the contractile mechanism: by binding to sites on the membrane, calcium ions are able to inactivate certain potential-sensitive channels and can thus inhibit their own entry into the cell.[31,32] The results of our studies of resistance vessel function, taken in conjunction with the work of others on membrane function, are thus consistent with the view that a calcium-binding disorder accounts for the increased activity of the potential-sensitive system in primary hypertension. A disorder of this type, which could well be genetic in origin, may be an important factor in the development and maintenance of increased peripheral resistance. Thus insights into the mechanism of vascular smooth muscle contraction gained from the use of calcium-entry blockers are proving of major assistance in furthering understanding of the nature of the functional changes in the resistance vessels in primary hypertension.

Pharmacokinetics of Calcium-Entry Blockers

R. G. McALLISTER, Jr., MD, SCOTT R. HAMANN, PhD, and ROBERT A. BLOUIN, PharmD

Effective use of drugs in therapy depends not only on clinical acumen but also on the availability of relevant pharmacokinetic and pharmacodynamic data. Such information assists in development of safe dosing regimens, prediction of abnormal handling of drugs in states of disease and disorder and anticipation of drug interactions. For the calcium-entry blocking agents now available in the United States (verapamil, nifedipine and diltiazem), these data appeared well after clinical patterns of use evolved. Nonetheless, their relevance continues to be demonstrated by the dependence of each agent on intact liver blood flow and function for normal rates of elimination; by the nonlinear kinetic characteristics for verapamil and diltiazem (and probably for nifedipine, as well) and the derivative implications for decreased dosing frequency requirements; and by observations now appearing on the relation between plasma drug levels and drug effects, both therapeutic and toxic. Such data are discussed herein, with emphasis on those aspects that impact on the clinical use of the calcium-entry antagonists.

(Am J Cardiol 1985;55:30B–40B)

The clinically relevant pharmacokinetic characteristics of any drug may have profound implications at the bedside. The term "pharmacokinetics" incorporates both demonstrated facts and inferred assumptions about a drug's absorption, distribution, metabolism and elimination in patients. Furthermore, the relation between the intensity and duration of therapeutic and toxic actions of a drug is inherent in pharmacokinetic profiles. Such information must be available to support the development of rational dosing regimens, to anticipate the probability of interactions with other therapeutic agents and to predict deviations from expected patterns in drug handling by patients with various disorders. Good medical practice is clearly dependent on an understanding of the pharmacokinetic characteristics of drugs prescribed.

The clinician frequently incorporates pharmacokinetic principles[1–3] into his or her use of therapeutic agents but infrequently recognizes this intuitive approach. We will briefly review selected aspects of kinetics that fall into this category and that may serve as a basis for subsequent consideration of the kinetic characteristics of specific calcium-entry blocking agents.

Drug absorption after oral administration may vary because of the characteristics of the chemical drug substance or its formulation. After intravenous administration, all the drug given is available for distribution to target tissues. The ratio of the amount of drug available to sites of action after an oral dose to that available after intravenous administration is called the bioavailability of a drug (usually labelled as F and reported as a percentage of the intravenous dose). Although the absorption process itself may limit bioavailability, the role of the liver in extracting absorbed drug from the portal circulation is generally more important. This "first-pass" effect may vary substantially among subjects and may account for wide variation in doses of specific drugs required for desired effects in different persons. For drugs not subject to hepatic metabolism, first-pass extraction is not a major consideration.

Drug distribution from the central compartment (such as circulating blood) to peripheral tissues occurs at variable rates, which will determine the time required to accumulate drug at sites of action to the critical concentrations required for therapeutic effects. This is a dynamic process, with elimination beginning even as distribution proceeds. The rate and extent of a drug's distribution to target tissues may vary substantially with systemic versus oral dosing,[4] resulting in differences in observed effects between the 2 dosing routes

F (%) = bioavailability; IV = intravenous; PO = orally; T/2$^{\beta}$ = elimination half-life; Vd (area) = apparent volume of distribution estimated from the area under the plasma concentration versus time curve.

that cannot be attributed to absorption or first-pass extraction variables.

Drug elimination from the body may more often be considered as a first-order process, in which the rate of elimination is directly proportional to the concentration of the drug remaining in the body. The kinetic characteristics of the calcium-entry blocking agents studied thus far are consistent with first-order disposition. In the presence of this type of nonsaturated elimination, the *rate* of drug elimination can be described by mono- or poly-exponential equations derived from serial measurements, after dosing, of drug concentrations in blood versus time. From the slope of the terminal linear phase of such data plotted in semilogarithmic fashion may be derived a rate constant for elimination, which itself is used to calculate a more familiar term, *the drug half-life*—the time required for drug levels in blood (or plasma) to decrease by 50%.

Another useful concept is *clearance*, which is defined as the volume of blood (or plasma) cleared of drug per unit time. If a specific drug is subject to clearance by the liver, for example, and its clearance is dependent on its rate of delivery to the liver, the drug's rate of elimination will depend upon liver blood flow (that is, flow-dependent clearance). In clinical conditions in which liver blood flow is altered, as in portal hypertension, the clearance will be significantly changed, with the attendant implications of drug accumulation and potential toxicity. Alterations in drug clearance affect drug half-life in reciprocal fashion; as clearance increases, half-life decreases.

During *long-term drug administration*, whether by continuous intravenous infusion or repeated oral doses, accumulation to steady-state or plateau concentrations may be predicted from the half-life: over 1 half-life unit, 50% of steady-state concentrations will be achieved, and over 5 half-life units, 97% of plateau levels will be present. When a drug has a long half-life, loading doses may be required to achieve rapid blood/tissue concentrations in the therapeutic range. Only recently has the nonlinear accumulation of drugs been widely recognized; in this circumstance, drug accumulation well beyond that predicted from the "5 × half-life" rule may be seen. This phenomenon may result from changes in the pharmacokinetic characteristics of a drug deriving from its own hemodynamic or metabolic effects. For example, the profound vascular actions of the calcium-entry blocking agents may actually reduce liver blood flow by dilating other regional vascular beds, thereby reducing the hepatic clearance of the drugs themselves. The pharmacokinetic profiles for drugs with significant hemodynamic actions may differ during long-term dosing from the profiles seen after single-dose studies. Therefore, predictions derived from single-dose kinetics must be viewed as approximations until confirmed by evaluations carried out during long-term drug administration.

As each of these variables is considered singly and in combination with others, the underlying assumption is that the concentration of the drug at specific sites of action is directly related to the effects observed, whether therapeutic or toxic, and, further, that the levels of drug at these tissue sites are related, loosely or intimately, to concentrations measured in blood. This principle of *pharmacodynamics* may be particularly useful in consideration of the calcium-entry blocking drugs, because they have, as a group, profound hemodynamic or electrophysiologic effects or both, and concomitant potential for therapeutic and toxic activity.

Verapamil

Although verapamil was introduced approximately 20 years ago in Germany, detailed descriptions of its pharmacokinetic characteristics did not become available until the late 1970s because of slow development of analytical methods capable of measuring concentrations of the drug in plasma with requisite sensitivity and specificity. At the present time, both high pressure liquid chromatographic and gas chromatographic techniques can be used to measure levels of the parent drug and its major metabolites.[5–10]

The pharmacokinetics of verapamil in normal subjects after single intravenous and oral doses are listed in Table I and Figures 1 and 2. Interestingly, the half-life after intravenous administration is similar to that seen after oral drug administration.[11] During long-term oral administration, nonlinear accumulation of the drug occurs, with reduced clearance and prolongation of the half-life value.[12,13] This latter observation has clinical importance: it implies that verapamil in its current oral formulation may be administered on a twice-daily schedule after accumulation to steady state has occurred, although most clinical studies have used regimens requiring 3 or 4 doses per day.

Verapamil is eliminated exclusively by the liver;[14] metabolism is effected by a cytochrome P450 system, in which Michaelis-Menten kinetics are demonstrable[15] (Fig. 3) and for which phenobarbital induction and SKF

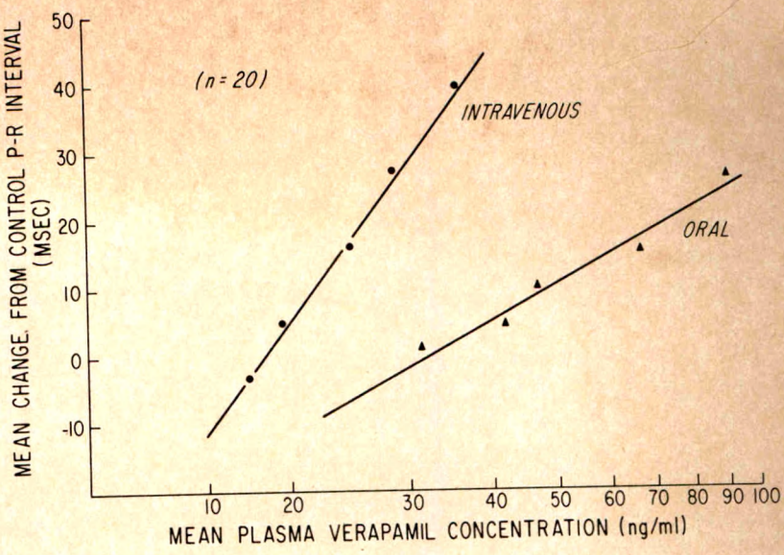

FIGURE 4. Plasma verapamil concentration versus mean change in P-R interval from control, after 10-mg intravenous and 80-mg single oral doses, in 20 normal subjects. Note differences in slopes and position of plasma level-effect lines (data from McAllister et al[11]).

525A suppression have been demonstrated.[16] Of the various metabolites,[17] only the N-demethylated form (norverapamil) has significant activity, which is only about 20% of the parent drug in studies with coronary vascular strips *in vitro*.[18] In the presence of normal liver function, oral verapamil is subject to extensive first-pass extraction, such that oral bioavailability is only about 20% (Table I). In patients with hepatic cirrhosis, first-pass effects are diminished, clearance decreased and bioavailability enhanced; drug accumulation to toxic levels may occur in such patients during administration of conventional doses.[19] In patients with chronic atrial fibrillation, higher bioavailability (35%) and longer half-life values (6 to 8 hours) were reported by Kates et al;[20] Anderson et al,[21] in a similar patient group, found half-life values similar to those in normal subjects but reduced bioavailability and clearance. It is possible that the presence of arrhythmia in these 2 study groups contributed to relative decreases in cardiac output and liver blood flow, thereby decreasing drug clearance. Further kinetic studies in patient groups are clearly desirable.

Verapamil has been reported to be highly bound to plasma proteins,[22] including both albumin and α-1 acid glycoprotein.[23] The latter protein appears to be largely responsible for binding variability seen in patients with supraventricular tachycardias. Verapamil can be displaced from binding sites in vitro by lidocaine, diazepam, propranolol and disopyramide.[24] These observations have not yet been validated by in vivo studies, and no clinically important drug interactions deriving from binding-site displacement of verapamil have been reported.

The plasma level-effect relations for verapamil are complex. After intravenous drug administration, a linear relation between drug levels and effects on atrioventricular conduction can be seen[11,25] (Fig. 4); at plasma levels <250 ng/ml, vasodilation occurs and cardiac output increases, but above this level, negative inotropic effects become evident and cardiac output decreases progressively[26] (Fig. 5). The electrophysiologic effects of verapamil occur preferentially, with the result that atrioventricular block is likely to occur before substantial hemodynamic toxicity is manifest.[26,27] (Fig. 6). When basal left ventricular pump function is significantly impaired, negative inotropic effects of verapamil are manifest at lower drug plasma levels.[28] After oral drug administration, plasma concentrations of verapamil required for specific effects on atrioventricular conduction are 2- to 3-fold higher than after intravenous dosing[11,25] (Fig. 4). Eichelbaum et al[29] suggested that this is due to preferential first-pass extraction of the relatively more active L-isomer of verapamil, whereas Hamann et al[4] reported data suggesting that tissue distribution patterns of verapamil

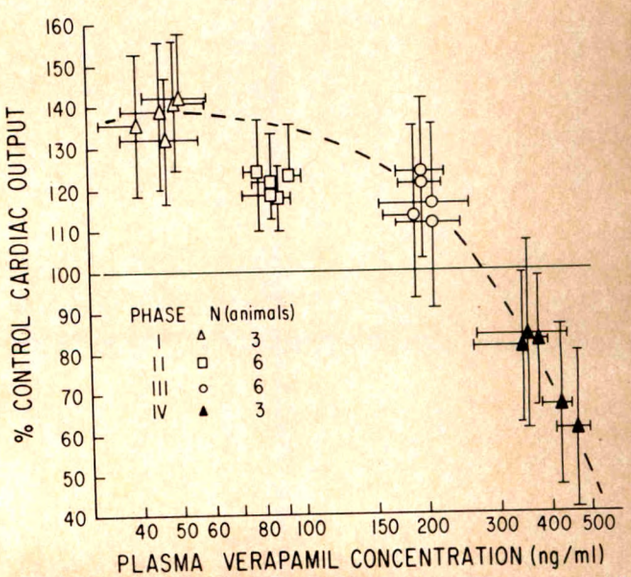

FIGURE 5. Correlation between plasma concentrations of verapamil during constant intravenous infusions and percent change in cardiac output from control levels, in mongrel dogs anesthetized with pentobarbital. Data points reflect means of observations made at 20, 30, 40, 50 and 60 minutes after beginning verapamil administration. At levels of about 250 ng/ml, direct negative inotropic effects of verapamil begin to become apparent.

c. = approximate (calculated from data in report); Cmax = peak plasma nifedipine concentration; Tmax = time to peak plasma concentration. Other abbreviations as in Table I.

differ after intravenous as opposed to oral dosing routes and, thus, intensity of drug effects may vary. In addition, the plasma concentration-response relation for verapamil is also significantly affected by variations in sympathetic tone,[11] resulting in wide differences in the plasma drug levels at which specific drug effects occur in different subjects.

Owing, in part, to verapamil's high first-pass extraction, concentrations of verapamil in plasma after administration of the same oral dose to different subjects vary by more than a 10-fold factor (Fig. 7). This observation alone makes the measurement of plasma concentrations of verapamil primarily of research interest and of little clinical importance except to demonstrate noncompliance or abnormal drug handling.

A sustained-release preparation of verapamil was evaluated by Follath et al,[30] who found stable plasma drug concentrations throughout 12-hour dosing intervals. In view of the demonstrated accumulation with conventional verapamil tablets, and the observed prolongation in half-life, the pharmacokinetic rationale for a sustained-release preparation of this drug is obscure.

Further aspects of the pharmacokinetic and pharmacodynamic profiles for verapamil have been reviewed recently.[31–33]

Nifedipine

Nifedipine is a dihydropyridine compound that is eliminated by hepatic metabolism.[34] Metabolism conforms to Michaelis-Menton kinetics (that is, the rate of metabolic elimination is related to the concentration of drug present) in isolated liver homogenate systems (Fig. 8); studies from our laboratory indicate that induction and suppression of metabolism do not occur as they do with verapamil.[16] All metabolites identified are dehydrogenated and pharmacologically inactive.[35] The drug is reported to be 90% bound to plasma proteins.[34]

The pharmacokinetic characteristics of nifedipine are only now being analyzed and reported in detail[35–38] because of early difficulties in development of sensitive and specific assay techniques. Early studies with nifedipine used a fluorimetric procedure, which may measure metabolites as well as unchanged drug.[39]

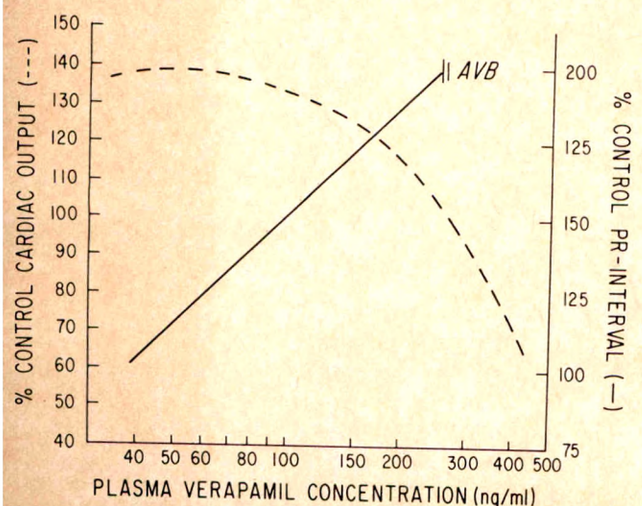

FIGURE 6. In same animals from which data were shown in Figure 5, data from cardiac output and P-R interval changes from control are combined. At plasma drug concentrations (during intravenous infusions to steady-state drug levels) >250 ng/ml, complete atrioventricular block was present and cardiac output depression was approximately at control levels, indicating preferential effects of verapamil on cardiac conduction system.

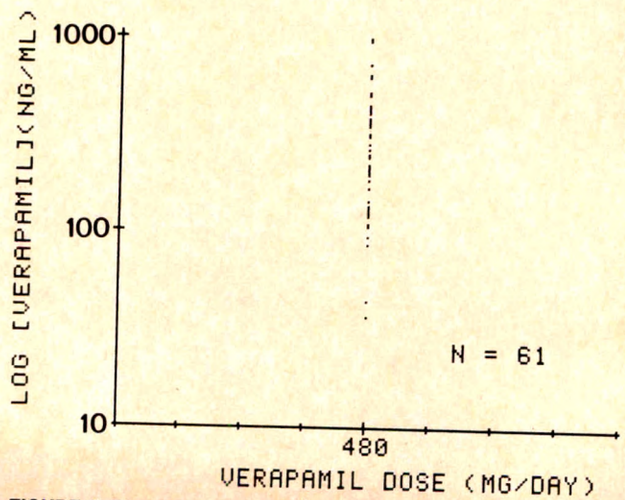

FIGURE 7. Plasma verapamil concentrations 2 hours after dosing in 18 men treated chronically with 480 mg/day of verapamil; 61 plasma samples were analyzed. Each point represents 1 plasma level determination. Scatter among subjects is more than 10-fold.

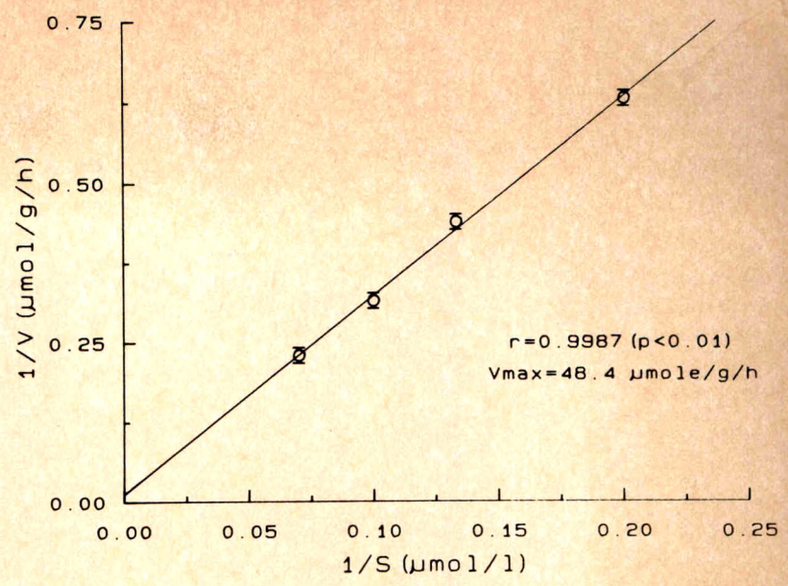

FIGURE 8. Metabolism of nifedipine by rat liver microsomes, shown in Lineweaver-Burk format. No saturation was seen, even at higher concentrations. S = substrate concentration; V = rate of metabolism.

Subsequent work used mass spectrometry,[40] gas chromatography with electron-capture detection,[41–43] and high pressure liquid chromatography.[44] Nifedipine is light-sensitive and rapidly decomposes in solvent when exposed to ordinary light sources; in plasma, however, it appears to be stable for up to 1 hour.[42] It has been suggested that various metabolite forms found in different studies[41] were artifacts from breakdown of nifedipine in solution.[35]

Pharmacokinetic profiles for nifedipine after intravenous administration were reported by Raemsch and Sommer[35] and by Foster et al[36]; both studies were done in normal subjects and used equivalent doses of nifedipine. The results were similar and are shown in Table II. Studies with 2- and 3-mg intravenous doses were performed in our laboratories (Foster et al, unpublished observations); analysis is difficult and requires model-independent approaches, as previously noted by others,[35] because of variation among subjects. Examples of plasma level versus time plots for intravenous nifedipine dosing are shown in Figures 9 and 10. Although these are preliminary results, elimination half-life appears to be prolonged at the 3-mg intravenous dose compared with 1-mg dose, and clearance is decreased. In a study with anesthetized dogs given intravenous nifedipine, we found that clearance was linearly related to liver plasma flow (Fig. 11) (an observation consistent with flow-limited clearance characteristics) and, further, that both clearance and hepatic plasma flow were inversely related to steady-state plasma drug concentrations. The difficulty in analyzing the pharmacokinetics of this drug when higher plasma levels are produced may relate in part to a nonlinear kinetic profile. Further studies are needed to confirm this in patients.

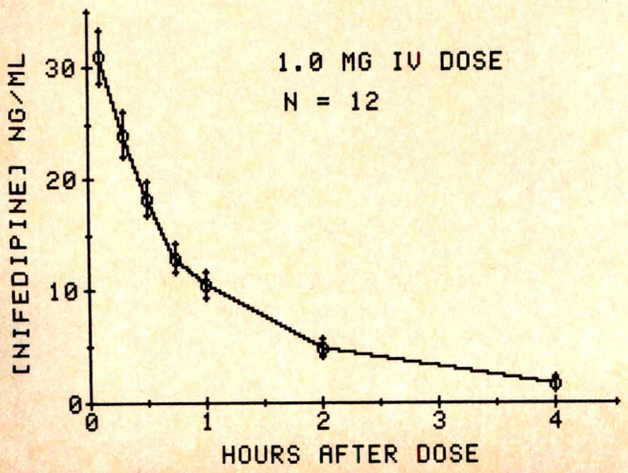

FIGURE 9. Plasma concentrations of nifedipine after intravenous administration of 1 mg to 12 normal volunteer subjects (data from Foster et al[36]).

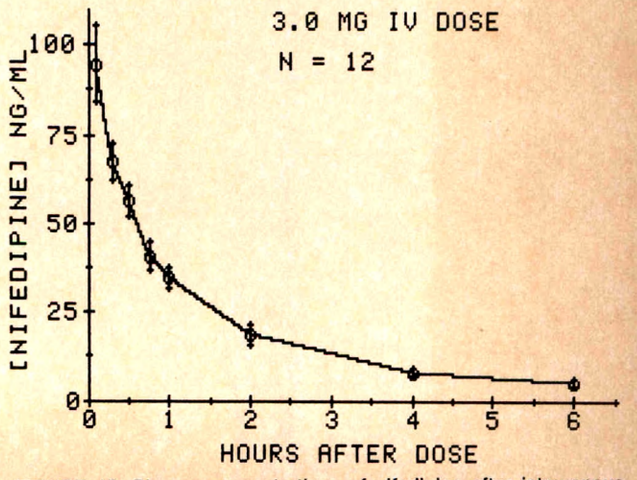

FIGURE 10. Plasma concentrations of nifedipine after intravenous administration of 3 mg to 12 normal volunteer subjects; note that peak plasma levels were 3 times higher than seen with 1 mg doses (Fig. 9). Dosing was carried out under gold fluorescent light to prevent photodegradation of nifedipine.

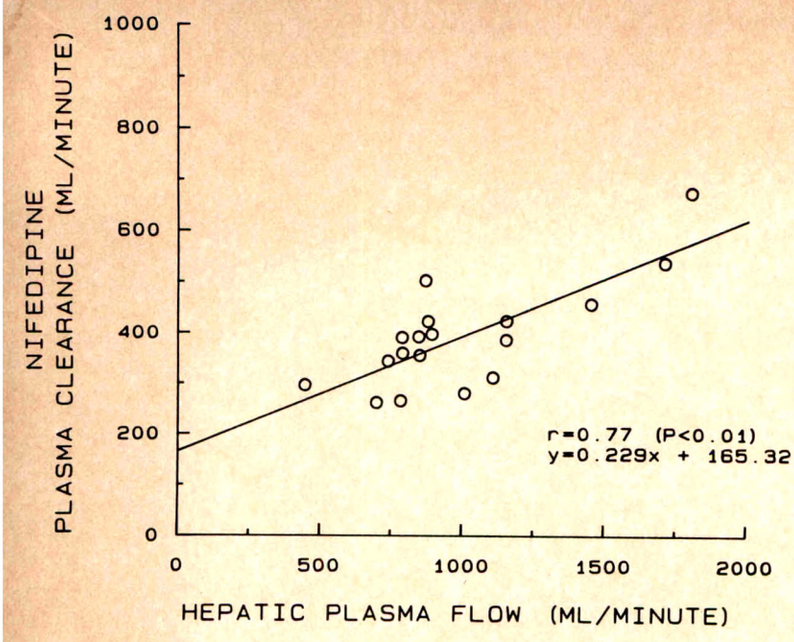

FIGURE 11. Nifedipine plasma clearance versus hepatic blood flow in dogs during pentothal anesthesia. Nifedipine was given intravenously in single doses. These data suggest that nifedipine clearance is, like that of verapamil, a function of hepatic blood flow.

Nifedipine is available in both a liquid-filled capsule and a tablet formulation; only the former is marketed in the United States, although both are available in other countries. The 2 preparations have distinctly different pharmacokinetic properties. Studies in normal subjects given the capsule (10 mg) were reported[35,36] and results are listed in Table II. With the capsule formulation, peak plasma drug levels occurred about 30 minutes after dosing, and elimination half-life values were about double those found with single intravenous doses. Calculated bioavailability ranged from 45% in the study by Foster et al[36] to 62% in the report from Raemsch and Sommer.[35] Wide variation among subjects was found in the former study; 4 of 12 study subjects had a kinetic profile suggesting delayed drug absorption, with peak plasma levels found 4 hours after dosing, which reached only about 25% of the peaks found in the other subjects.

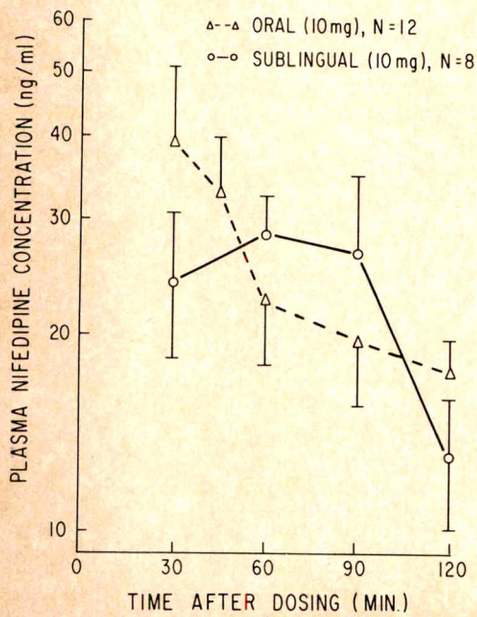

FIGURE 12. Comparison of plasma nifedipine levels after oral administration of single 10-mg capsule (in 12 normal subjects) and sublingual dosing with same preparation (in 8 normal subjects). (Oral data from Foster et al.[36]) Sublingual values were obtained in different but comparable study population. Plasma drug levels after sublingual dosing reach significantly lower peak values, at a later time, than are seen with oral capsule ingestion.

Sublingual administration of the 10-mg capsule was noted by Raemsch and Sommer[35] to produce plasma level peaks lower than those seen after equivalent oral doses; studies from our laboratories have confirmed this in various groups of subjects (Fig. 12). Although sublingual drug administration is widely thought to produce drug effects more rapidly and to a greater intensity than oral administration, current data with the capsule formulation indicate that, in fact, the opposite is often true.

Results from pharmacokinetic evaluation of hypertensive patients[37,38] given nifedipine in tablet form are also listed in Table II. The time to peak plasma levels after the tablet was given is about 3 times that seen with the capsule, and the half-life is 4-fold lengthened. In tablet form, therefore, twice-daily nifedipine dosing is appropriate, whereas the capsule must be given more frequently. Accumulation apparently does not occur with frequently used doses of nifedipine.[35]

Plasma level-effect relation for nifedipine are not as yet well established. In studies with dogs given intravenous nifedipine by infusion, Hamann and McAllister[45] found linear relations between hemodynamic effects (decreases in arterial pressure, increases in cardiac output [Fig. 13]) over a wide plasma level range; no electrocardiographic changes were seen. In hypertensive patients, using the tablet preparation, Taburet[38] reported a significant correlation between plasma concentrations of nifedipine and observed decreases in supine mean arterial pressure, over a range of drug levels

TABLE III Diltiazem Pharmacokinetics[54]

Abbreviations as in Tables I and II.

from 10 to 250 ng/ml. Although Aoki et al[46] found a similar, if less significant, correlation, Pedersen et al[47]—using nifedipine capsules—found none. These differences may lie in the analytical methods used to measure drug plasma concentrations, the various nifedipine formulations given to the patient subjects, the plasma levels of drug achieved and sustained in different patients or some combination of these factors.

Diltiazem

Diltiazem is a benzothiazepine derivative initially evaluated in Japan.[48] Studies in dogs revealed virtually complete drug absorption after oral administration, with a high first-pass effect[49]; bioavailability of the commercial tablet preparation was 24%.[50] In various species studied, diltiazem was subject to extensive hepatic metabolism, with the major elimination pathway involving deacetylation.[49,50]

With the development of sensitive and specific assay methods for diltiazem estimation in plasma,[51,52] clinically relevant data in patients have rapidly become available. In an early study with orally administered diltiazem, Kinney et al[53] reported that single doses of 30 mg produced plasma drug levels barely measurable; 60, 90 and 120-mg doses resulted in progressively larger areas under the plasma drug level versus time curve. There was a slight prolongation in half-life values as doses increased.

In 8 normal subjects, Smith et al[54] studied the pharmacokinetic properties of diltiazem after intravenous infusions, single oral doses and repeated oral administration (Table III). Triexponential elimination kinetics were observed after both systemic and oral drug administration, and the terminal half-life values were similar with each study protocol (3.7 to 4.5 hours). During long-term oral drug dosing, accumulation of both the unchanged diltiazem and the deacetylated metabolite was observed. Evidence of enterohepatic recirculation was deduced from double peaks often seen in plasma concentration versus time curves. Of partic-

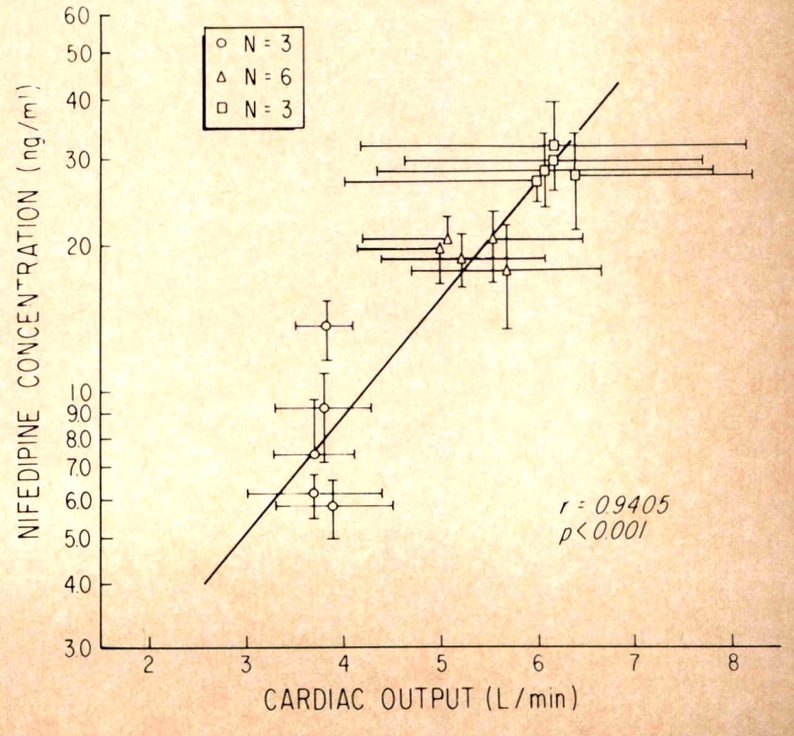

FIGURE 13. Plasma concentrations of nifedipine versus cardiac output. Data were obtained in dogs anesthetized with pentothal. Reproduced with permission from *J Cardiovasc Pharmacol*.[45] No evidence of negative inotropic effects is seen, even at higher drug concentrations, where 50% increase in cardiac output occurs.

ular interest was the observation that bioavailability after initial oral doses (38%) increased to 90% with continued drug administration, without changes in elimination half-time values. Smith et al attributed this observation to saturation of the metabolic elimination pathway for diltiazem.

A similar study involving only single intravenous and oral doses of diltiazem was reported by Hermann et al,[55] who found half-life values of 3.1 hours after both intravenous and oral doses; bioavailability varied from 24 to 74% (mean: 42) due to differences in first-pass effects among subjects.

In patients with advanced renal failure, single doses of diltiazem (120 mg) were eliminated with a half-life of 3.4 hours,[56] not significantly different from findings in normal subjects.

Diltiazem is 80% bound to serum proteins, and binding was independent of drug concentration.[57] Drug binding was not altered by the presence (in therapeutic concentrations) of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid or warfarin.

Preliminary studies in dogs[58] and patients[59] suggest that diltiazem plasma concentrations may be related to both the hemodynamic and electrophysiologic effects of the drug. Further work will be required to define the plasma drug levels associated with specific therapeutic and toxic effects.

Drug Interactions

The calcium-channel blocking drugs are particularly useful in patients with various types of cardiovascular disorders, a population in which polypharmacy is widely practiced and often appropriate. It is not surprising, then, that interactions with other drugs are being observed, some of which may have distinct clinical significance.

When verapamil is added to a regimen that includes digoxin, plasma glycoside concentrations increase about 75%[60,61] because of verapamil-related decreases in digoxin clearance by the kidney.[62] In some clinical studies, this occurrence has been held responsible for an increased incidence of digitalis toxicity,[60,63] although others have not confirmed this.[61] In an animal model, we showed that concomitant administration of verapamil and acetylstrophanthidin markedly *increases* the dose of glycoside required to produce electrophysiologic toxicity, compared with that needed when glycoside is given alone.[64] Therefore, although the pharmacokinetic aspects of the verapamil-digoxin interaction are well demonstrated, the clinical consequences are not at all clear, and the need to decrease glycoside doses when verapamil is added is not well established. A similar interaction between diltiazem and digoxin, in which renal digoxin clearance was reduced and plasma glycoside levels increased, was recently reported.[65] There is more controversy about the results of coadministration of nifedipine and digoxin; whereas Belz et al[66] found an increase in digoxin levels after addition of nifedipine, Pedersen et al[67] reported that nifedipine dosing produced no significant alterations in digoxin pharmcokinetics.

Another area of interest involves interactions between calcium-entry blockers and anesthetics. Although halothane and catecholamines are an established arrhythmogenic combination, Kapur and Flacke[68,69] have shown that verapamil produces a sustained increase in the arrhythmogenic threshold, which persists even when plasma drug concentrations are too low to produce measurable hemodynamic effects. Isoflurane is a volatile anesthetic with myocardial depressant properties that are enhanced by the addition of verapamil.[70] In the isolated rat heart, the combination of halothane and nifedipine appears to produce additive negative inotropic effects,[71] whereas in the intact dog anesthetized with halothane, nifedipine produced marked hypotension due to peripheral vasodilation and attenuated reflex compensatory heart rate increases.[72] During fentanyl-pancuronium anesthesia in patients, the hemodynamic effects of nifedipine included a negative inotropic effect without sustained vasodilation.[73] The pharmacokinetic aspects of these interactions have not yet been studied.

A considerable body of literature is evolving on the combined use of β-adrenoceptor blocking drugs and calcium-entry antagonists. Because nifedipine appears to act predominantly as an arterial vasodilator, its combination with β blockers would appear to be a reasonable attempt to blunt the reflex heart rate increase accompanying drug-related decreases in peripheral vascular resistance; in patients with angina who have reasonable exercise tolerance, this combination was termed by Dargie et al[74] a *beneficial drug interaction.* However, there is evidence that nifedipine does indeed have negative chronotropic and inotropic effects, which are normally masked by compensatory sympathetic activity; in the presence of β blockade, therefore, the potential for electrophysiologic toxicity and depression of left ventricular contractile function may become manifest.[75,76] The combination is, however, widely used and appears to be generally without significant hazard in the absence of profoundly impaired ventricular pump activity.

With verapamil, in contrast, the dose-related negative inotropic effects[77] may be exaggerated when it is given with a β blocker. This was clearly shown in the report from Packer et al,[78] in which patients with angina treated with therapeutic doses of propranolol (producing plasma drug levels >100 ng/ml), were given 40-, 80- and 120-mg oral doses of verapamil; this resulted in dose-dependent decreases in cardiac performance. Repeat administration of the 120-mg verapamil dose after withdrawal of propranolol produced no significant cardiodepressant effects, emphasizing the negative inotropic potential of this drug combination. Furthermore, animal studies in our laboratories have documented a propranolol-related decrease in liver blood flow, which reduces the clearance of verapamil and permits accumulation of the drug to toxic plasma concentrations during continuing verapamil administration.[79] The pharmcokinetic aspects of this interaction are complex and depend upon the order of administration of the drugs, the doses of each used, the plasma

levels produced and the underlying state of the myocardium. Because the potentially toxic effects of the interaction depend to a considerable degree on plasma level-related drug effects, it is not surprising that clinical studies with stable subjects and fixed-dose drug administration protocols have not generally reported deleterious consequences from the combination.[80,81] Similar clinical studies are also appearing for diltiazem–β-blocker combinations, and with similar results.[82] Despite the complex pharmacokinetic results from the coadministration of calcium-entry blockers and β-adrenoceptor antagonists, it seems clear that abolition of sympathetic chronotropic and inotropic influences in the myocardium may permit unwanted actions of the calcium blockers to become manifest[83] and, in addition, that such a combination of drugs must be used clinically with considerable caution.[84]

Cimetidine, which has pronounced effects on both liver blood flow and drug metabolizing enzyme systems, might be expected to alter the elimination kinetics of nifedipine, diltiazem and verapamil, because each calcium-blocker agent is subject to hepatic disposition; no controlled trials have yet been reported.

In summary, the clinical use of verapamil, nifedipine and diltiazem has evolved on a largely empiric basis; the bedside application of these agents has preceded definitions of their clinically relevant pharmacokinetic and pharmacodynamic profiles. However, studies are now appearing that may substantially alter the ways in which these drugs are used. For instance, the demonstration of reduced clearance of verapamil with long-term oral administration implies that twice-daily dosing may be sufficient, in contrast to the 3 or 4 daily doses recommended by the manufacturer. The same may be true for diltiazem, but further studies are required. The importance of intact hepatic function and perfusion status with all these agents has emerged from kinetic studies, resulting in the need for an appropriate degree of clinical caution when the drugs are used in patients in whom liver abnormalities may be present. Furthermore, pharmacodynamic studies relating plasma drug concentrations of each of the 3 available calcium-entry blockers to their observable effects are now being reported. These data, together with pharmacokinetic observations, should assist in efforts to characterize patients who do not respond satisfactorily to therapy into appropriate categories. Interactions with other drugs appear to have both kinetic and dynamic aspects of considerable clinical consequence, especially when β-receptor blockers and the calcium-entry antagonists are given together. Finally, progress in defining the clinical kinetics and dynamics with these prototypic agents should help to focus investigation of newer drugs as they evolve.

Large Vessel Coronary Vasospasm: Diagnosis, Natural History and Treatment

C. RICHARD CONTI, MD

The diagnosis of coronary artery spasm is confirmed by angiography, for example, change in caliber of the coronary arteries plus evidence of ischemia. The prevalence and contribution of coronary artery spasm in the individual patient with symptoms of ischemic heart disease is not known and depends on how the condition is defined. The prognosis of patients with coronary artery spasm appears to depend on the presence or absence of severe coronary atherosclerosis, that is, those with severe disease have a worse prognosis. Nitrates should be used to initiate therapy in all patients with this problem. Intravenous nitrates have proven useful in patients whose symptoms are difficult to control and who require hospitalization. β blockers used alone may be detrimental in patients with coronary artery spasm, but studies supporting the detrimental effects are few. The combination of nitrates, β blockers and nifedipine has proved effective therapy for many patients with recurrent angina at rest, possibly related to coronary artery spasm. Several open-label and double-blind placebo control trials have shown that all of the calcium antagonists are effective short-term agents for patients with proven coronary artery spasm. When nifedipine was compared with isosorbide dinitrate in a randomized crossover, double-blind trial in patients with coronary artery spasm, both drugs were shown to be efficacious and neither was superior.

The traditional α-blocking agents have not been shown to be an effective therapy, but a recent study of prazosin, a selective α blocker, revealed excellent results in patients whose conditions were resistant to therapy with traditional calcium blockers, β blockers and, in 1 case, phenoxybenzamine. Another study, however, showed no beneficial effect. α-β blockers, anticholinergic drugs, aspirin and prostacylin have not been shown to be effective treatment for coronary artery spasm. In patients with "refractory coronary artery spasm" it may be necessary to use intracoronary nitroglycerin, combinations of calcium antagonist alone or with nitrates, or prazosin therapy to control symptoms. Although the reason is not clear, a few cases have responded to therapy with intraaortic balloon counter pulsation. Coronary artery bypass surgery with and without denervation procedures is effective in many patients with obvious obstructive coronary stenosis, in addition to coronary artery spasm related to the underlying coronary lesions. However, results are not as good in those patients as in patients with fixed coronary stenosis and no evidence of coronary artery spasm.

(Am J Cardiol 1985;55:41B–49B)

It is my belief that coronary artery vasomotion plays an important role in the pathophysiologic features of the various conditions resulting from myocardial ischemia. However, I do not believe that coronary artery spasm is the only mechanism to explain the clinical manifestations of ischemic heart disease. Figure 1 schematically illustrates the theoretical contribution of fixed and dynamic coronary artery stenosis to the origin of myocardial ischemia. Four factors are considered: (1) physiologic features, such as coronary blood flow and myocardial oxygen demand, (2) the percentage of coronary artery stenosis secondary to atherosclerosis, (3) the clinical presentation of angina and (4), postulated mechanism responsible for the ischemic cardiac pain.

At one extreme (Fig. 1, left) is the patient group with normal or near normal coronary arteries. The most common clinical presentation is angina at rest. Because there is no limitation of coronary blood flow caused by atherosclerosis, the most logical physiologic event responsible for this chest pain is a decrease in coronary blood flow rather than an increase in myocardial oxygen demand. Thus, the hypothetical mechanism most likely responsible for chest pain in these patients with "normal" coronary arteries is abnormal constriction of the coronary arteries or vasospasm.

From the Division of Cardiology, College of Medicine, Department of Medicine, University of Florida, Gainesville, Florida.

Address for reprints: C. Richard Conti, MD, Division of Cardiology, College of Medicine, Department of Medicine, University of Florida, Gainesville, Florida 32610.

In contrast, at the other extreme (Fig. 1, right) is the patient group with severe fixed stenosis >90% secondary to coronary artery disease. These patients' chest pain syndrome is most likely related to effort and the physiologic event is increased myocardial oxygen consumption in the setting of fixed coronary reserve. Thus, the mechanism for chest pain in such patients is the presence of severe coronary atherosclerosis.

The patient group in the center of Figure 1 (those with 50 to 60% coronary artery stenosis) may present with chest pain at rest or with variable effort. The physiologic event occurring in these persons is transient decrease in caliber of the coronary arteries producing a decrease in coronary blood flow associated with an increase in myocardial oxygen demand secondary to exercise. Thus, the most likely mechanism is related to the combination of significant artery disease plus vasomotion abnormalities of the coronary arteries.

The patient group that presents with prolonged angina at rest is represented in Figure 1, far right. These are the type of persons who could be considered as having an unstable condition or being in the process of evolving myocardial infarction. As many studies indicate, patients with unstable angina and evolving myocardial infarction generally have significant atherosclerosis. It is possible that a slight change in caliber of the arteries, such as increased tone, may transiently occlude coronary blood flow without any corresponding increase in myocardial oxygen demand and thus produce severe ischemia. It is also possible that a transient thrombosis of this severely narrowed coronary artery may produce the same result, for example prolonged angina at rest. If the tone is relaxed or the thrombosis is lysed, then this severe chest pain syndrome can be called unstable angina. If the increased tone persists or the thrombosis is not lysed, then an acute evolving myocardial infarction will result.

Any unstable ischemic syndrome can develop from any of these clinical presentations. For example, the patient with normal or near normal coronary arteries can have repetitive episodes of coronary artery spasm that make his condition unstable, thus putting him into the same category as the patient with severe coronary stenosis and mild changes in tone or repetitive episodes of thrombosis. In this fourth category with severe stenosis and either increased tone or repetitive thrombosis, the major mechanism is related to the presence of severe coronary artery disease.

Diagnosis of Coronary Artery Spasm

Some confusion exists because the term *coronary artery spasm* has been used interchangeably with the specific clinical syndrome of *variant angina* or *Prinzmetal's angina pectoris*. The term variant angina should be reserved for patients whose only symptoms are chest pain at rest associated with transient ST-segment elevation on the electrocardiogram (ECG). This is a relatively uncommon clinical presentation of angina pectoris.

I have found the following to be a useful working definition of coronary artery spasm: a transient decrease in lumen diameter of an epicardial coronary artery of sufficient degree to produce myocardial ischemia, in the absence of increased heart rate and blood pressure, which is promptly reversed by nitroglycerin. This definition does not set limits on the degree of lumen diameter decrease required to produce ischemia, and it can be applied to patients with normal as well as diseased coronary arteries. The frequently associated manifestations of myocardial ischemia are chest pain and ST-segment elevation or depression on the ECG. However, neither symptoms nor ST-segment elevation are always present during repeated episodes of angina in the same patient who, on other occasions, may have ST-segment elevation and associated coronary lumen decrease.

Coronary artery spasm should not be diagnosed unless there is evidence, such as angiography and ischemia,

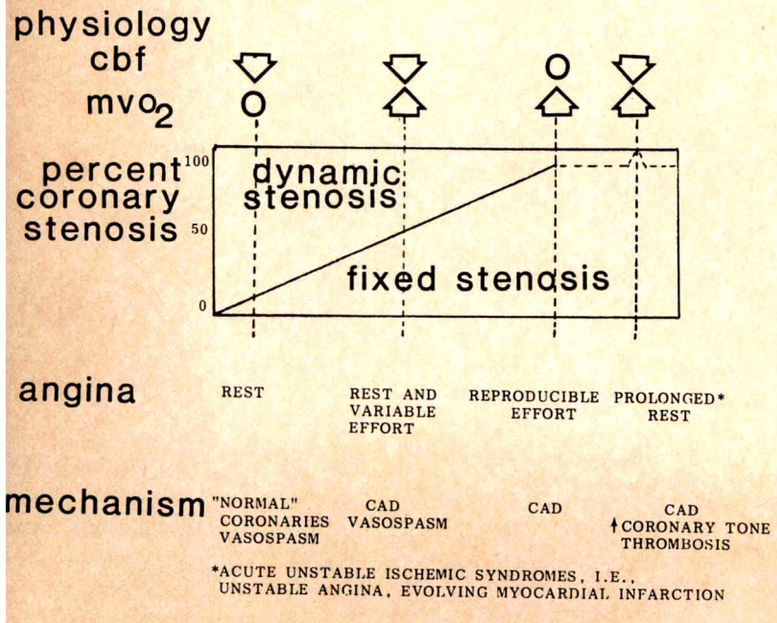

FIGURE 1. Schematic illustration of theoretical contribution of fixed and dynamic coronary artery stenosis to etiology of myocardial ischemia. CAD = coronary artery disease; CBF = coronary blood flow; $M\dot{V}O_2$ = myocardial oxygen demand.

TABLE I "Natural" History of Coronary Artery Spasm

Study	Diagnosis	Patients (n)	Mean Duration of Follow-Up	Death	Myocardial Infarction	Angina	Remission
Selzer et al[1]	Variant angina	16	...	3	1	...	...
Severi et al[2]	Angina at rest	138	4 years	12	32	...	...
University of Florida	Coronary spasm	27	1 year	3	5	4	15
Waters et al[3]	Variant angina	132	1 month	5	13	...	...
Bott-Silverman et al[4]	Coronary spasm	59	6 years	0	11	25	23
Waters et al[5]	Variant angina	169	12 months	19	34	...	...
Waters et al[6]	Variant angina	100	12 months	...	...	55	45

to support the diagnosis. This evidence can be obtained at the time of coronary angiography if the patient has spontaneous angina pectoris or if angina is provoked by an agent such as ergonovine maleate. Patients with chest pain and transient ST-segment elevation on routine exercise or ambulatory ECG should be presumptively diagnosed as having coronary artery spasm.

Unfortunately, ST-segment elevation does not prove that patients have coronary artery spasm. However, it does suggest that angina is related to transient decrease in myocardial blood flow. The mechanism of the transient decrease in blood flow may differ according to coronary anatomy. For example, in a patient with normal coronary arteries or <50% stenosis, the most likely cause of ST-segment elevation is spasm. Thrombotic occlusion theoretically could occur in the setting of prolonged spasm and a myocardial infarction could evolve. In a patient with >50% but <70% stenosis of the coronary artery, spasm and subsequent thrombosis may still occur. However, because of the significant coronary artery disease, stasis and turbulence may enhance platelet aggregation and thrombosis could occur in the absence of spasm. In a patient with >70% and <90% stenosis, turbulent flow, stasis and platelet aggregation can account for in situ thrombosis as a primary mechanism, but the possibility of spasm as well should not be excluded. In the patient with >90% stenosis of the coronary artery, it is reasonable to hypothesize that coronary artery thrombosis occurs as a primary event. This concept is illustrated in Figure 2. If the thrombosis is transient, the patient might have transient ST-segment elevation and be labeled as having either Prinzmetal's or unstable angina. If the thrombosis is permanent, myocardial infarction may evolve.

A probable diagnosis of spasm can be considered in patients who have the syndrome of variant angina, that is, angina at rest, associated with ST-segment elevation on the ECG. A high degree of suspicion for coronary artery spasm exists in patients who have angina at rest, especially those with unstable angina. Additionally, one can be suspicious of spasm in patients who have variable effort angina or walk-through angina. Coronary artery spasm is a possibility in patients with acute myocardial infarction or acute reinfarction and in patients with normal coronary arteries who die suddenly.

Natural History

It is unlikely that patients with coronary spasm are a homogenous group. A common variable is the presence or absence of severe coronary artery disease. Although only a few reports are available, it seems as though spasm in association with coronary artery disease has a more malignant course than does coronary spasm in patients with minimal or no coronary disease. However, a few cases of coronary vasospasm in patients with normal coronary arteries have resulted in ventricular fibrillation and heart block, so that even in this setting, the condition is not benign. Results of several reports are listed in Table I.

Selzer et al[1] reported observations in 16 patients with variant angina. Nine patients with minimal or no coronary artery disease had no serious events during follow up. In contrast, 4 of 7 patients with coronary artery disease had an acute myocardial infarction, and 3 of these patients died. Severi et al[2] studied 138 patients, 9 of whom had angiographically normal coronary arteries. In the first month of follow up, 28 had nonfatal myocardial infarctions and 5 died. From 1 to 4 years after therapy, 7 additional patients died and 4 had acute myocardial infarction. At the University of Florida, 27 patients with coronary artery spasm and coronary artery disease were treated with calcium antagonists for 1 year. During the course of follow up, 3 died, there were 5

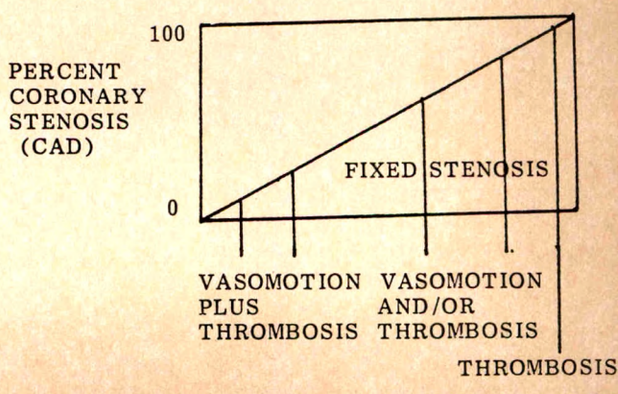

FIGURE 2. Theoretical relation of coronary artery disease, vasomotion and thrombosis in patients with myocardial infarction. CAD = coronary artery disease.

nonfatal myocardial infarctions, 4 patients had severe angina pectoris requiring hospitalization and 15 had a "good response" to medical therapy.

Waters et al,[3] at the Montreal Heart Institute, reported the prognosis of 132 patients with variant angina at 1-month follow up. Most of the patients were treated with calcium antagonists. Five patients died and 13 had nonfatal myocardial infarction. Of the remaining 114 patients, none either had a myocardial infarction or died. The investigators noted a tendency toward single-vessel disease in patients without myocardial infarction or death and multiple-vessel disease in the 18 patients who died or had myocardial infarction. Bott-Silverman and Heupler[4] reported the clinical course of 59 patients with coronary spasm with angiographically normal or near normal coronary arteries. Average follow-up time was 5.9 years. They noted spontaneous remission in 39% of patients; 24% were long-term and 15% were short-term. In addition, 19% of patients had a myocardial infarction, 10% required permanent pacemakers and no patient died.

Waters et al[5] reported a study of 169 consecutive patients hospitalized for variant angina who were studied for a mean of 15.3 months (range 1 to 68). At 1 year, the survival rate was 95% but there was a 20% nonfatal myocardial infarction rate. At 3 years, the overall survival rate was 87%. Most complications occurred within the first 3 months after diagnosis.

Waters et al[6] also assessed the prevalence of spontaneous remission in 100 patients with variant angina with a follow up of at least 1 year. Remission was diagnosed in 45 of the 100 patients who had been angina-free and who had no treatment for >3 months (mean 18.3). Based on these observations, the investigators believe that variant angina should be considered a "temporary condition." They advise that "drug therapy can probably be discontinued at some point in most patients with a history of variant angina," and they usually begin to taper and discontinue treatment 6 to 12 months after angina disappears.

Treatment

Current Drug Therapy for Patients With Proved or Suspected Coronary Artery Spasm

The goal of therapy for patients with proven coronary artery spasm should be the prevention of myocardial ischemia rather than prevention of recurrent attacks of pain, because myocardial ischemia can occur in the absence of chest discomfort. Ideally, it is desirable to have an objective endpoint of therapy, for example, decrease in frequency of ST-segment shifts with or without pain. Theoretically, prevention of myocardial ischemia episodes should result in a decrease of malignant ventricular arrhythmias and, possibly, a decrease in the incidence of myocardial infarction and sudden death.

Nitrates: Perhaps the best way to initiate therapy, regardless of clinical presentation or ECG manifestations, is with nitrates. Traditionally, long-acting, sublingual, oral or topical nitrates have been used to prevent recurrent episodes of angina at rest, whereas individual attacks have been treated with sublingual nitrates.

The recent availability of commercially prepared intravenous glyceryl trinitrate has facilitated the management of many acute cardiac conditions, including recurrent angina at rest. Page et al[7] treated 67 patients with an intravenous preparation. Therapy was initiated during the first days of hospitalization and the dose was increased every 10 to 30 minutes from 36 to 108 μg/min. Systolic arterial pressure was maintained >90 mm Hg. Intravenous nitrates were used in combination with β blockage in 34 patients and with nifedipine in 6 additional patients. In 21 patients, ECG changes were those of variant angina, that is, transient ST-segment elevation. The investigators noted a decrease in the mean number of anginal attacks from 9.83 ± 7.6 (previous 7 days) to 1.2 ± 2.45. The duration of treatment with intravenous nitrates varied from 2 to 29 days (mean: 7.4 ± 4.2). Sixty-four patients (95.5%) had improvement in symptoms during treatment with intravenous nitrates, 42 (62.7%) becoming free of pain, but 3 continued to have angina at the same rate as before nitrate therapy. Complications were noted in only a few patients; bradycardia and hypotension occurred in 2. These symptoms were reversed by decrease of infusion rate. Headaches were noted in 3 patients, requiring a decrease in the nitrate dose.

Beta blockers: In the experience of most clinicians, β blockers seem to control the symptoms of recurrent angina at rest regardless of the direction of the ST-segment shift during chest pain. It is not entirely clear why this should be the case. However, it must be remembered that β blockers have some effects that favorably influence perfusion of ischemic myocardium and prevent arrhythmias. For example, propranolol decreases platelet aggregation across the myocardium at rest and during pacing-induced tachycardia. It is also possible that factors initiating coronary vasospasm may be blocked by β-blocking agents. An additional factor that may account for the success of β blockers in treating this condition is the concomitant use of nitrates. Most physicians treating patients with recurrent angina use oral, topical or intravenous nitrates simultaneously with β blockers. Although the studies are few, one must acknowledge the potential detrimental effect on β blockers in patients with proven coronary artery spasm. Robertson et al,[8] using a double-blind protocol, investigated the use of propranolol in patients with coronary artery spasm as assessed by subjective and objective variables. Both small-dose (40 mg every 6 hours) and large dose (160 mg every 6 hours) propranolol were administered. At both doses, the duration of angina attacks was significantly prolonged but the frequency was not. There was considerable variability of patient response.

The β blockers that are relatively specific in low doses for the β_1 receptor warrant a trial in patients with coronary artery spasm. Some new β-blocking drugs possess intrinsic sympathomimetric activity. These agents act as β-receptor agonists as well as antagonists, so that the heart rate at rest tends to remain unchanged or even increase. These agents may provide the vasodilating

stimulus necessary to prevent coronary spasm. Current wisdom dictates that β blockers should not be used without a vasodilator in patients with proven coronary artery spasm.

Calcium antagonists: Most investigators report that patients with chest pain that is due to coronary artery spasm, who have continued symptoms despite nitrate and β blocker therapy, respond favorably to calcium-antagonist therapy.

Results using nitrates, β blockers and nifedipine: Hugenholtz et al[9] recently reported on 73 patients with unstable angina treated with maximum β-adrenergic blockade, nitrates and bed rest. Fifty-two of these patients remained symptomatic. After 60 mg of nifedipine administered orally for 24 hours was added to treatment, 42 patients became asymptomatic. The excellent clinical response to the drug in this group of patients with unstable angina pectoris indicates that calcium antagonists may play an important role in therapy, particularly when the cause of angina is suspected to be related to abnormal coronary vasomotion. Gerstenblith et al[10] randomly allocated 138 patients with unstable angina to either routine therapy with nitrates and β blockers or routine therapy with nitrates, β blockers and nifedipine. They showed that fewer patients had medical therapy failures (myocardial infarction, death or surgery) when given nifedipine compared with routine therapy. This difference was due primarily to the 52 patients who had transient ST-segment elevation associated with chest pain.

Antman et al[11] evaluated nifedipine in a large, open-label trial in patients with coronary artery spasm. They reported results of therapy in 127 patients with either angiographically documented coronary artery spasm, angina at rest with reversible ST-segment elevation or both. The patients were treated with nifedipine in dosage ranges from 40 to 160 mg/day. Other therapy, such as nitrates or β blockers or both, were continued or added to the treatment in many instances. Follow-up time averaged 9 months and 87% of patients had at ≥50% reduction in angina frequency; in 63%, angina was abolished.

Results using verapamil as monotherapy: Mehta et al[12] reported similarly encouraging results using the calcium-antagonist verapamil over a 5-day period. No therapy other than sublingual nitrates was used in the patients, and nitrates were used to treat individual attacks of pain. In this study, verapamil was compared with placebo in 15 patients, 4 who had ST-segment elevation with pain and 11 who had ST-segment depression with pain. Thirteen of these patients had >50% decrease in angina frequency when verapamil was compared with placebo. One patient had >50% decrease in angina frequency when placebo was compared with day 1 of the trial and 1 patient had no change in angina frequency when verapamil was compared with placebo, regardless of the dose of verapamil used. These results indicate that verapamil was an effective short-term agent for the management of patients admitted to the hospital for treatment of angina at rest.

Results using diltiazem: Because of a favorable preliminary report by Yasue et al,[13] a double-blind intervention using 2 dose schedules of diltiazem, 120 and 240 mg/day, in 11 patients with variant angina was performed.[14] With small dose therapy, 5 patients became asymptomatic or had >50% decrease in symptoms compared with placebo. When large-dose therapy was used, 6 patients became asymptomatic and 1 had >50% decrease in angina frequency. Diltiazem appeared to be remarkably free of adverse effects during this short-term trial. No patient showed evidence of rebound or increase in symptoms after withdrawal of this drug.

Results of comparison between nifedipine and isosorbide dinitrate in patients with coronary spasm[15]*:* The subjects for this study were 22 men and 4 women who had angina that occurred mostly at rest and was relieved by nitroglycerin. There was a 2-week lead-in phase during which calcium antagonists or topical nitrates or both were excluded from the treatment regimen. Patients who had >3 episodes of pain/week were entered into the double-blind randomized phase (treatment with either niefdipine or isosorbide dinitrate). After dose titration (40 to 120 mg/day) and evaluation, they were given the alternate therapy. During the course of the trial, the effects of nifedipine and isosorbide dinitrate on frequency of angina and consumption of nitroglycerin were evaluated by patient diary. Twenty-one patients completed all study phases. Two patients died, 1 in each group. Two patients could not tolerate isosorbide dinitrate because of headache and hypotension and an additional patient stopped the study medication because of poor response. In the 21 patients who completed all 3 study phases, the mean frequency of angina during the lead-in phase was 1.86 episodes/day. Compared with lead-in phase, the frequency of angina was significantly decreased for both nifedipine (0.71 episodes/day) and isosorbide dinitrate (0.66 episodes/day) (in both, $p < 0.05$). Likewise, nitroglycerin consumption was significantly decreased in the lead-in phase (2.09 tablets/day) when compared with both nifedipine (0.90 tablets/day) and isosorbide dinitrate (0.56 tablets/day) phases (in both, $p < 0.05$).

Individual patient responses to the drugs were analyzed. Compared with lead-in phase, angina frequency during the nifedipine phase was reduced by ≥50% in 18 of 24 patients. Six of these were asymptomatic. During the isosorbide dinitrate phase, 15 of the 21 patients had a >50% decrease in their angina frequency and 4 of these were asymptomatic. Eleven patients had this decrease in angina frequency during both nifedipine and isosorbide dinitrate phases. In addition, 6 patients receiving nifedipine and 6 patients taking isosorbide had <50% decrease in angina frequency.

When the entire group of 21 patients who completed all study phases was evaluated, 11 had >50% decrease in angina frequency with nifedipine compared with isosorbide dinitrate and 7 had >50% decrease in angina frequency with isosorbide dinitrate compared with nifedipine. The remaining 3 patients had a similar angina frequency with both drugs. This trial indicated that both nifedipine and isosorbide dinitrate were effective in certain patients with coronary spasm and neither drug was clearly superior.

Result of calcium-antagonist therapy in Japan: Although the aforementioned studies illustrate the effectiveness of these agents in the United States alone, practitioners around the world attest to their clinical usefulness. Kimura and Kishida[16] reviewed data from 11 cardiology institutes in Japan to determine the effectiveness of drug therapy, especially with calcium antagonists, in variant angina patients. The subjects were 243 men and 43 women. Coronary artery disease was found in 92 of 162 patients (56.7%) in whom coronary angiography was performed. Drugs were effective in 92.3% of patients with normal or near normal coronary arteries and 82.6% of those with >50% stenosis. The investigators interpret these findings to suggest that the drugs are effective because of their antispsamotic action.

Alpha-blocking agents: Alpha-blocking agents have received isolated and anecdotal attention, suggesting that they may be effective in preventing coronary spasm. If the α-adrenergic nervous system plays a major role in the genesis of coronary spasm in an individual patient, this mode of therapy would seem to be the logical choice. However, some experiences suggest that few patients respond to α-blockade therapy.

Recently Tzivoni et al[17] reported the successful treatment of Prinzmetal's angina in 6 patients using the selective α blocker prazosin. Therapeutic trials with large doses of nifedipine, verapamil, nitrates, β blockers and, in one case, phenoxybenzamine were ineffective in all 6 patients. Prazosin, 8 to 30 mg/day, combined with small-dose nitrates or nifedipine completely abolished the attacks in 4 patients, markedly reduced their frequency and intensity in 1 patient and had to be stopped in the sixth because of hypotension and dizziness. In 4 patients, discontinuation or decrease of prazosin resulted in exacerbation of symptoms but its renewal was followed by disappearance of the attacks. Mean follow-up period in the study was 4 to 6 months. Despite these encouraging results, Winniford et al[18] reported no obvious beneficial effect in 6 patients with variant angina randomized to prazosin or placebo over a 4.5-month period. Mean dose of prazosin was 14.0 ± 2.4 mg/day.

Alpha-beta-blocker therapy: A new class of adrenergic-blocking agents possesses both α- and β-blocking activity. Labetolol is the prototype agent of this class. In a recently published preliminary trial,[19] labetolol was reportedly effective in significantly reducing or abolishing the frequency of "spontaneous angina." If these episodes were due to coronary artery spasm, labetolol may warrant further study.

Anticholinergic therapy: Based upon reports largely from Japan, the cholinergic nervous system is implicated as the basis for coronary artery spasm in certain patients. Therefore, trials with anticholinergic agents were suggested. To date, the reports have been isolated and anecdotal, and some trials have shown that these agents are not useful in most patients with coronary artery spasm.

Results of antiplatelet therapy for coronary spasm: The observation that coronary spasm occurs frequently at sites of minimal atherosclerosis has led to the suggestion that vascular endothelium produces deficient amounts of PGI_2 in these atherosclerotic areas. Under conditions in which platelet adhesion and aggregation are increased, release of thromboxane A_2 would result in vasoconstriction. Increased peripheral levels of thromboxane B_2, the stable metabolite of thromboxane A_2, have been reported in some patients with variant angina. Because of these findings, treatment with antiplatelet agents has been suggested.

Chierchia et al[20] hypothesized that thromboxane A_2 released by aggregating platelets was a potential mediator of coronary vasospasm. They studied 7 patients with coronary artery spasm by continuous ECG monitoring for 2 days before and 2 days after a single small intravenous dose of aspirin (2 mg/kg). This dose reduced thromboxane B_2 to <3% of the control values. There were 129 transient ischemic episodes during control and 146 during aspirin therapy, when platelet thromboxane B_2 was reduced to negligible levels. Because the duration, severity and incidence of symptomatic episodes were not significantly affected by small-dose aspirin, thromboxane A_2 is probably not responsible for initiation of coronary vasospasm. In another study by Miwa et al[21] aspirin, 4 g/day, was administered orally to 4 patients with Prinzmetal's angina. The administration of aspirin markedly increased the frequency of angina attacks and attacks that had occurred only at night or in early morning during the control period also occurred in the daytime when the 4 patients were receiving aspirin. Exercise stress testing performed in the afternoon was repeatedly negative during the control period; it became positive during aspirin administration in 3 patients who were able to perform the test. The investigators concluded that a large amount of aspirin can aggravate coronary arterial spasm in cases of Prinzmetal's angina. Despite these negative observations, the concept that platelet aggregation may be responsible for initiating or aggravating spasm should not be ignored.

Several other methods to inhibit platelet aggregation are available, for example, other nonsteroidal antiinflammatory agents, stable PGI_2 analogues, PGI_2-releasing agents and specific inhibitors of thromboxane A_2. It should also be mentioned that certain calcium-blocking agents, in particular, verapamil and diltiazem, inhibit platelet aggregation. Studies of platelet-aggregation inhibitors should shed new light on the mechanisms of coronary spasm and provide avenues for treatment. At present, however, these agents are not recommended for the usual management of the patient with coronary artery spasm.

Effect of intravenous prostacyclin: Chierchia et al[22] evaluated the effects of intravenous PGI_2 in 9 patients with variant angina and 6 normal volunteers. In the normal subjects, with PGI_2 in 2.5, 5, 10 and 20 μg/kg/min, there was a significant antiplatelet effect and a dose-dependent decrease in both systolic and diastolic arterial pressure with a corresponding increase in heart rate. In 8 patients with proven coronary artery spasm, PGI_2 did not affect the number, severity or duration of spontaneous ischemic episodes due to coronary vasospasm. However, in 1 patient, the number of ischemic

episodes was consistently reduced during 4 consecutive periods of PGI_2 infusion alternated with placebo. The investigators conclude that while PGI_2 can be administered safely and may occasionally result in complete disappearance of ischemic episodes due to coronary vasospasm, it is usually ineffective.

Treatment of "refractory" coronary artery spasm: In Prinzmetal's description of variant angina,[23] he suggested that responsiveness to nitroglycerin was part of this syndrome. This idea is widely held. However, we recently studied 4 patients with coronary artery spasm who did not respond to the usual dosages of sublingual or intravenously administered nitroglycerin. In 2 of these patients, coronary artery spasm occurred in the right coronary artery, and in the other 2, spasm occurred in the anterior descending branch of the left coronary artery. Three of these patients (2 with right coronary spasm and 1 with anterior descending spasm) had hemodynamically important atherosclerotic obstruction at or near the site of spasm. In 3 of these patients, the refractory spasm occurred spontaneously during or shortly after coronary angiography, and in 1 the coronary spasm was provoked using ergonovine. In each case, coronary spasm responded promptly to *intracoronary* administration of small doses of nitroglycerin (25 to 100 μg). In 1 case, coronary spasm continued to recur at 25- to 30-minute intervals and was finally prevented with the institution of intraaortic balloon pumping. Whenever the balloon pump was transiently turned off, spasm recurred. The reason for the effectiveness of balloon pumping in this instance is unclear, but perhaps is related to the increased diastolic perfusion pressure in the affected coronary artery.

Recently, Buxton et al[24] reported on 5 patients with refractory ergonovine-induced coronary spasm. Three of these patients died, but in 2, intracoronary administration of nitroglycerin promptly reversed spasm. Maseri et al,[25] in a description of patients with unstable angina, reported on 6 patients in whom acute myocardial infarction developed shortly before, during or after coronary angiography. In these patients, intracoronary nitroglycerin was not effective in reversing spasm. Oliva and Breckinridge[26] identified 6 patients in whom intracoronary nitroglycerin reversed coronary spasm during the early phase of acute infarction. These reports stimulate speculation that refractory coronary artery spasm may be an important step in the evolution of myocardial infarction, sudden death and other ischemic heart disease syndromes.

Comparison of Medical and Surgical Treatment of Patients with Coronary Artery Stenosis and Evidence of Coronary Artery Spasm

With the exception of the National Heart, Lung, and Blood Institute trial for unstable angina,[27] published reports on the medical and surgical management of coronary artery spasm do not compare therapies. Rather, they chronicle events occurring in patients receiving medical or surgical treatment. Table II summarizes these reports.

Over the past 4 years, 21 patients at the University of Florida with coronary artery disease and coronary artery spasm underwent coronary artery bypass graft. Twenty patients survived the operation and 1 had a perioperative myocardial infarction. Of the 20 survivors, followed for an average of 3.5 years, 2 had a subsequent myocardial infarction, 1 died, 10 continued to have angina and 9 were symptom-free.

Surgical reports, from 1971 to 1977,[28] indicate that 89 patients underwent coronary artery bypass graft surgery for angina associated with ST-segment elevation. During a mean follow-up time of 12.2 months, there were 14 deaths and 13 nonfatal myocardial infarctions. Of the survivors, 24 continued to have angina and 51 were symptom-free.

Pasternak et al[29] studied 54 patients with variant angina, 38 of whom underwent coronary artery bypass surgery. Total follow-up time in these patients averaged 32.3 months (range: 7 to 79). Of the 38 patients undergoing surgery, there were 3 hospital deaths (7.8%), 3 hospital myocardial infarctions (7.8%), 2 late deaths and 2 late myocardial infarctions. Over the long-term follow

up, they reported improvement in symptoms in 28 of 33 survivors of surgery (85%). In the 16 patients who did not undergo surgery, there was 1 hospital myocardial infarction and 1 late death. In the 15 survivors, 8 (53%) had satisfactory control of their symptoms. Based on these observations, the authors recommend coronary artery bypass graft surgery in those patients with variant angina who have severely stenotic, fixed atherosclerotic lesions and in whom medical management has failed.

Schick et al[30] published in 1982 the results of surgery in 52 patients with coronary artery spasm and coronary artery disease. All surgery took place from 1973 to 1979. They divided their patients into those who had angina without infarction (40) and those who had angina in the early postinfarction state (12). Of the 40 patients with angina without infarction, there was a mean follow-up time of approximately 30 months. There were no deaths, 7 nonfatal myocardial infarctions and 33 patients without a significant event in this group. In the same group, 10 continued to have angina syndrome and 30 were symptom-free. In contrast, in the 12 postinfarction angina patients, mean follow-up time was also approximately 30 months but 3 patients died and 2 had another nonfatal myocardial infarction. Seven patients were alive without subsequent event. Of the 9 patients alive, 2 continued to have angina and 7 were symptom-free.

In the National Heart, Lung, and Blood Institute trial,[27] 79 patients had chest pain associated with ST-segment elevation. Mean follow-up time was 42 months for both the 42 patients treated medically and the 37 patients treated surgically. In the medical group there were 3 deaths, 6 nonfatal myocardial infarctions and 33 patients who had no events. Of the 39 surviving patients, 29 continued to have angina syndrome and 10 were symptom-free. In contrast, in the 37 surgically treated patients there were 6 deaths, 10 nonfatal myocardial infarctions and 21 patients without a significant event. Of the 31 survivors, 5 continued to have angina and 26 were symptom-free.

In 1980, Bertrand et al[31] published their study comparing coronary bypass surgery with coronary artery bypass graft plus plexectomy in patients with coronary artery spasm and coronary artery disease. The mean follow-up time of the 13 patients undergoing coronary artery bypass graft was 36 months. In this group there was 1 nonfatal myocardial infarction, 2 deaths, 2 who continued to have angina and 2 who were documented as having continued coronary artery spasm. In the 22 patients undergoing coronary artery bypass graft and plexectomy, the mean follow-up time was 20 months. There were no nonfatal myocardial infarctions; there were 2 deaths, 1 continued to have angina and 1 was documented as having coronary artery spasm.

Based on these reports, it seems reasonable to try vigorous dilator therapy before surgery in these patients. If pain or asymptomatic myocardial ischemia persists despite drug therapy, the patient should be considered for coronary artery surgery. However, current results of surgery for patients with this condition may not be as good as those in patients who have typical effort angina and no evidence of coronary artery spasm. Although speculative, this difference may be due in part to spasm occurring along the entire length of the coronary artery, proximal and distal to a fixed obstruction. If surgery is performed, coronary vasodilator therapy should be continued postoperatively with the goal of decreasing the possibility of recurrent coronary artery spasm distal to the bypass graft insertion or in other vessels.

In summary, most patients with syndromes related to coronary spasm respond to nitrates. Nitrates are extremely safe, thus their use for relief or prevention of the acute ischemic episode remains the initial treatment of choice. When symptoms are more than mild-to-moderate in severity or unacceptably controlled in frequency using nitrates alone, other pharmacologic measures are needed. In patients who also have effort angina, suggesting a hemodynamically important atherosclerotic type obstruction in addition to spasm, β-adrenergic–blocking drugs can be helpful. If effort angina remains unacceptably controlled or adverse effects occur, calcium antagonists may be added or substituted. Where the predominant symptom is angina at rest and the patient has other evidence suggesting coronary artery spasm, use of a calcium antagonist usually produces a favorable response. This therapy should be extended not only to patients in whom spasm occurs spontaneously, but also to those in whom it can be provoked by such stimuli as effort or cold. When spasm is superimposed upon hemodynamically important atherosclerotic obstruction, the favorable response to calcium antagonists may not be as great as that seen when spasm exists alone. In these cases, coronary artery bypass surgery may be required to control symptoms. Recommendation for surgery, however, requires demonstration that spasm is occurring in and about the area of fixed atherosclerotic obstruction and not occurring in other vessels or over the entire course of distal vessel.

Chest Pain and "Normal" Coronary Arteries—Role of Small Coronary Arteries

RICHARD O. CANNON III, MD, MARTIN B. LEON, MD, RITA M. WATSON, MD, DOUGLAS R. ROSING, MD, and STEPHEN E. EPSTEIN, MD

To study the mechanism of chest pain in patients with insignificant epicardial coronary artery disease, 50 patients underwent great cardiac vein (GCV) flow, oxygen content and lactate determinations at rest and during pacing, and left ventricular end-diastolic pressure (LVEDP) measurements at rest and after pacing. Twenty-four patients having typical chest discomfort during pacing demonstrated significantly lower increase in flow from baseline (36 ± 18% versus 86 ± 24%, p <0.001) and decrease in coronary resistance (−17 ± 12% versus −43 ± 7%, p <0.001) compared with 26 patients without pacing-induced chest pain, despite no significant difference in myocardial oxygen consumption ($M\dot{V}O_2$) between the 2 groups. Lactate consumption at a heart rate (HR) of 150 beats/min was significantly less (28.3 ± 21.5 versus 51.3 ± 35.8 mM·ml/min, p <0.001) and the increase in LVEDP from rest to after pacing was significantly greater (5 ± 2 versus 1 ± 2 mm Hg, p <0.001) in the chest pain group. After administration of ergonovine, 0.15 mg intravenously, to 46 of these patients, 31 had typical pain either at rest (1 patient) or during pacing. This group had significantly lower increase in flow (38 ± 20% versus 107 ± 38%, p <0.001), and decrease in coronary resistance (−16 ± 12% versus −45 ± 11%, p <0.001) compared with the 15 patients not having chest pain, despite no significant difference in $M\dot{V}O_2$ between the 2 groups. Patients with chest pain also had lower lactate consumption at a HR of 150 beats/min (39.2 ± 23.6 versus 65.3 ± 46.3 mM·ml/min, p <0.01), greater arterial-GCV oxygen difference (12.5 ± 1.3 versus 11.6 ± 1.0 ml O_2/100 ml, p <0.05), and a more marked increase in LVEDP from rest to after pacing (11 ± 3 versus 5 ± 2 mm Hg, p <0.001). Quantitative coronary arteriography demonstrated no significant luminal narrowing of the epicardial coronary arteries in response to ergonovine. These data are consistent with the hypothesis that some patients with chest pain and angiographically normal epicardial coronary arteries have dynamic abnormalities of the small coronary arteries or coronary microcirculation that cause abnormal vasodilator reserve or vasoconstriction, resulting in myocardial ischemia and angina pectoris. (Am J Cardiol 1985;55:50B–60B)

Angina pectoris in patients whose epicardial coronary arteries appear to be normal or near normal with angiography is a frequent clinical occurrence. In fact, one fourth of the patients entered prospectively into the Coronary Artery Surgical Study (CASS) fell into this category.[1] Although some of these patients may have epicardial coronary artery spasm,[2] this subset is probably quite small because Prinzmetal's or variant angina is relatively uncommon.[3] Despite multiple explanations for chest pain in the presence of normal coronary arteries, an extensive evaluation often fails to reveal an alternative cardiac or noncardiac mechanism, a frustrating experience for both physician and patient.

From the Cardiology Branch, Cardiovascular Diagnosis Section, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland.

Address for reprints: Richard O. Cannon III, MD, Room 7B-15, Building 10, National Institutes of Health, Bethesda, Maryland 20205.

Since 1982 we have evaluated over 50 patients with chest pain and angiographically normal coronary arteries. The pain described was usually qualitatively similar to ischemic cardiac pain: it was located substernally, often radiated to the neck and arms and frequently was associated with shortness of breath. The pain was "atypical" only in that its threshold of onset was variable, it often occurred at rest and occasionally nocturnally and was variably relieved by nitrates. Patients often said chest pain occurred toward the end of the day or after strenuous activity. The results of our studies designed to elucidate a possible cardiac mechanism for these patients' chest pain are presented.

Methods

Fifty consecutive patients with chest pain syndromes but with normal epicardial coronary arteries and no known heart disease were evaluated using the protocol described later. The

TABLE I Clinical Profile of Patients Entering Study

Characteristic	NVR (n = 13)	AVR (n = 37)
Hypertension	3	10
Cigarette use		
Active	0	9
Remote	4	5
Diabetes mellitus (insulin-requiring)	0	4
Myocardial infarction	0	6
Alcohol abuse	0	6

results of our first study of 16 patients were reported previously.[4] Ten of the patients were believed, on the basis of history and physical examination, to have musculoskeletal or other noncardiac cause for their chest pain. This determination was made before the patient's entry into the study. The remaining 40 patients gave histories consistent with ischemic cardiac pain.

A minority of patients were insulin-requiring diabetic, smoking or hypertensive subjects (Table I). Most patients were in good general health until adult life when chest pain was first experienced. Although these patients were often reassured as to the benign nature of their chest pain on the basis of previous noninvasive and invasive testing, most considered their pain to be cardiac in origin, significantly debilitating and warranting further evaluation. The majority of patients had electrocardiograms (ECGs) obtained during episodes of chest pain—none showed ≥1 mm ST-segment shifts, and most remained unchanged (Table II). Six patients were reported by their referring physician to have had myocardial infarctions. A careful physical examination was performed before the study, with attention to musculoskeletal chest wall tenderness.[5] All patients underwent bicycle exercise testing using a National Institutes of Health protocol[6]; 2 had >1 mm horizontal or downsloping ST depression. The remaining patients had nonspecific ST-T–wave changes or no change in 12-lead recording during and after exercise (Table II). M-mode ECGs were performed in all patients and 2-D ECGs in the majority: none had evidence of hypertrophic cardiomyopathy and 3 had mitral valve prolapse.

Medications were discontinued in all patients and 48 hours or more later each patient underwent cardiac catheterization. Routine diagnostic coronary arteriography, using multiple angulated views, was first performed. Although in our previous study[4] some patients were included who had significant narrowing of a coronary artery other than the left anterior descending coronary artery, only patients with normal epicardial arteries, or minor wall placquing, were included in the present study (Table III). An 8Fr pigtail fluid-filled (12 patients) or micromanometer-tipped (Millar Instruments) catheter was positioned in the left ventricle of the last 24 patients studied. A Swan-Ganz thermodilution balloon-tipped catheter (Edwards Laboratories) was positioned in a peripheral pulmonary artery in 41 patients. A thermodilution pacing catheter[7] (Elecath Corporation) was introduced through the right internal jugular vein and advanced through the coronary sinus into the great cardiac vein (GCV), which drains approximately 90% of the anterior myocardial circulation (left anterior descending and diagonal branches).[8,9] Catheter stability was maintained throughout the entire study by frequent position checks using fluoroscopy and by repeat baseline rest flow determinations. A 20-gauge Teflon catheter was placed in the left brachial artery for blood pressure monitoring and recording.

The study protocol was initiated at least 30 minutes after use of contrast material so that any effects of dye on coronary blood flow or metabolism would subside.[10] The present series consists of 50 consecutive patients in whom GCV flow measurements were successfully obtained using the protocol described later. GCV flow (50 patients), lactate (50 patients) and oxygen content (32 patients) were determined at rest, as were measurements of cardiac index (CI) (41 patients), mean pulmonary artery wedge pressure (PCW) (41 patients), and left ventricular end-diastolic pressure (LVEDP) (24 patients). Pacing through the coronary sinus catheter was initiated at a heart rate (HR) of 100 beats/min, and increased by 10 beats/min increments at 1-minute intervals up to a HR of 150 beats/min. In 13 patients, atropine, 0.5 to 1.0 mg, was administered intravenously to achieve a HR of 150 beats/min. In 2 patients, pacing was terminated at a HR of 130 beats/min. At the final HR, repeat GCV flow and lactate, arterial and GCV oxygen content, and CI measurements were made. Pacing was then terminated and LVEDP and PCW were monitored after pacing in 24 patients for 10 seconds and averaged, eliminating the first 4 postpacing beats. Arteriography of the left coronary artery was performed in 2 views 90° apart for quantitative measurement of epicardial coronary artery caliber.

After a rest period of 20 minutes to allow any contrast media-induced alteration of coronary blood flow or metabolism to subside, we again measured baseline GCV flow, lactate, arterial and GCV oxygen contents, and PCW and LVED pressures. Repeat baseline measurements were not made in Patient 14, because of persistent atropine-induced tachycardia. Ergonovine, 0.15 mg, was then administered intrave-

p values determined comparing patients developing versus those not developing chest pain.
* Atropine.
† $p < 0.001$.
BP = mean arterial blood pressure; CR = coronary resistance; GCV-F = great cardiac vein flow; HR = heart rate; % ΔF = percent change in GCV-F from rest; % ΔR = percent change in CR from rest; SD = standard deviation.

nously to 46 patients (the remaining 4 patients participated in other studies). Although the patients were aware that ergonovine would be administered sometime during the study, the actual administration of the drug was performed without their knowledge. Repeat measurements of GCV flow were performed at 45 seconds and immediately thereafter pacing was initiated at a HR of 130 beats/min. Pacing was then increased to 150 beats/min with repeat measurements as described for the control study, after which time pacing was discontinued, and LVED and PCW pressures were measured for 10 seconds. Arteriography was then performed (approximately 4 minutes after administration of ergonovine) in the same views as the control study. The majority of patients received an additional 0.25 mg of ergonovine with repeat arteriograms.

Measurement analysis: The thermodilution method for determining GCV flow has been described previously.[7,9–11] Coronary resistance was calculated as the mean arterial pressure divided by GCV flow. Coronary sinus flow measurements were not recorded because of concern for possible right atrial reflux during pacing.[12] Leads I, II and III were recorded during the studies for the first 16 patients, and leads I, AVF and V_5 during the studies for the remaining 34 patients. Lactate samples were obtained from the artery and GCV and collected in tubes containing potassium oxalate and sodium fluoride for red blood cell glycolytic inhibition. The samples were immediately centrifuged at 5,000 rpm for 10 minutes at 4°C and the serum was decanted and refrigerated in the catheterization laboratory. Specimens were analyzed on a Dupont automatic clinical analyzer by a modification of the technique of Marbach and Weil.[13] Lactate consumption was calculated as GCV flow multiplied by the difference between arterial and GVC lactate concentrations. Blood oxygen content was measured by a Lex-O_2-Con-K oxygen analyzer (Lexington Instruments) with frequent duplicate determinations and at least 1 change of scrubber gas during the course of the study. Arterial-venous oxygen (AVO_2) difference represented arterial minus GCV oxygen content, and myocardial oxygen consumption ($M\dot{V}O_2$) was determined by the product of GCV flow and AVO_2 difference, representing oxygen consumption in the anterior left ventricle and interventricular septum.

Arteriograms of the coronary arteries for quantitative measurement were always obtained in 2 views 90° apart, usually 60° left anterior oblique and 30° right anterior oblique, using Siemens-Elema equipment with C-Arm so that the patient was not moved during the study. The developed films were projected on a Vanguard cine-projector at approximately 3× magnification. In 14 patients, 10 × 12 cm cut films were obtained at 2 films/s for 3 seconds. For either angiographic technique, coronary artery luminal diameter was measured using calipers at multiple positions along the proximal, mid and distal epicardial arteries. Measurements were made by 2 observers without knowledge of the catheterization results, using the known dimensions of the 8Fr Judkins left coronary catheter as a reference measurement. Care was taken to use frames in which the region of interest was centered on the screen or cut film to avoid magnification and other distortion artifacts. Measurements were made at identical points in the 2 views, using branch arteries as references, and were averaged.

Data were analyzed using Student's t test for paired and unpaired data with a probability value <0.05 considered significant. All grouped data are reported as mean ± standard deviation.

Results

Control study: The mean baseline GCV flow for the control study (Table IV) was similar to that of previously published studies using the thermodilution method.[7,9,14,15] During the control pacing study, 2 symptomatic responses were elicited; 24 patients had their typical chest discomfort, and 26 reported either no chest discomfort or pacing-related chest sensations that were clearly different from their typical spontaneously occurring chest pain. Table IV contains the heart rate, mean blood pressure, GCV flow and calculated coronary resistance at rest and during pacing at a heart rate of 150 beats/min (130 beats/min in 2 patients). Figure 1A displays the absolute GCV flow at rest, during intermediate pacing (130 beats/min in most patients) and final pacing in all 50 patients. Those patients not having chest pain had a significantly higher flow response (124 ± 27 ml/min) than those patients having their typical chest discomfort (98 ± 26 ml/min, $p <0.001$). Calculated coronary resistance (Fig. 1B) decreased less in the 24 patients having their typical chest discomfort, a difference that was significant at both intermediate (1.25 ± 0.43 versus 1.03 ± 0.22 mm Hg/ml/min, $p <0.025$) and final pacing rate (1.20 ± 0.37 versus 0.86 ± 0.25 mm Hg/ml/min, $p <0.001$).

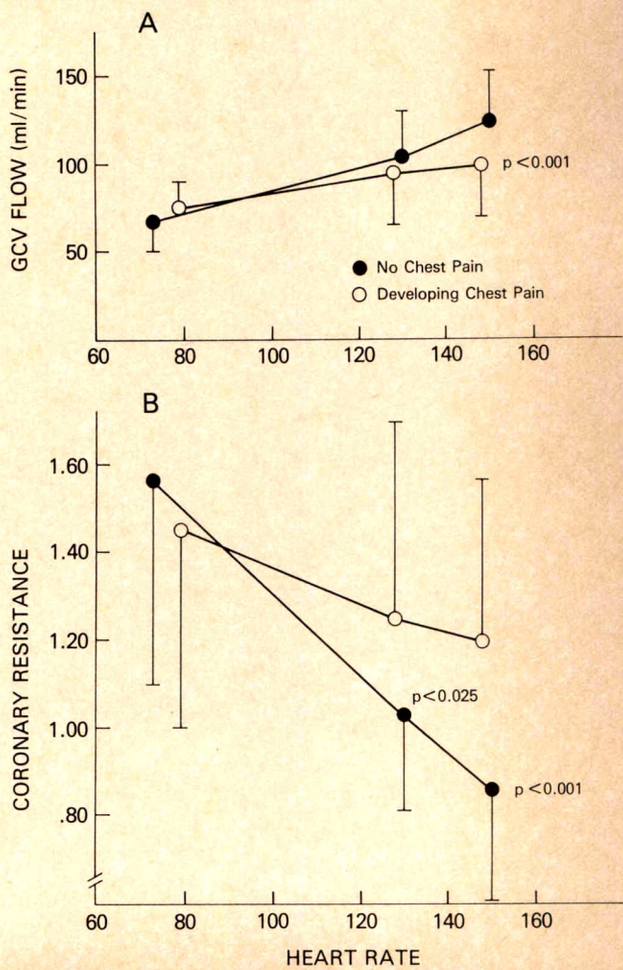

FIGURE 1. Great cardiac vein (GCV) flow (**A**) and calculated coronary resistance (**B**) during control study in 50 patients at rest and during intermediate and high-paced heart rates. **Closed circles** represent group without chest pain; **open circles** represent group having their typical chest pain during pacing. Circles represent mean values ± standard deviation.

Because the portion of anterior circulation coronary flow drained by the GCV may vary from person to person[8] (although it averages approximately 90% of left anterior descending flow), the percent change in GCV flow and coronary resistance from rest to maximal pacing was also calculated, so that each person served as his or her own control (Table IV). Flow increased less in those patients having their typical chest discomfort during pacing (36 ± 18% versus 86 ± 24%, p <0.001) than it did in the patients without chest pain (Table IV, Fig. 2). Likewise, coronary resistance decreased less in those patients having chest pain (−17 ± 12% versus −43 ± 7%, p <0.001) that it did in the patients without chest pain. Lactate consumption at a HR of 150 beats/min (Fig. 3) was significantly lower in those patients experiencing chest pain compared with those without chest pain (28.3 ± 21.5 versus 51.3 ± 35.8 mM·ml/min, p <0.001) because lactate consumption increased less or actually decreased during pacing. During pacing, AVO_2 difference decreased significantly (12.4 ± 1.7 at rest to 11.6 ± 1.5 ml O_2/100 ml during pacing, p <0.001) in those patients without chest pain, whereas the AVO_2 difference was unchanged in those patients having chest pain (11.6 ± 1.3 at rest to 11.6 ± 1.7 ml O_2/100 ml during pacing), as demonstrated in Figure 4. Despite the significant difference in GCV flow between the 2 groups, the $M\dot{V}O_2$ and systolic blood pressure-heart rate product were not significantly different at maximal pacing (Table V).

The cardiac index at rest was similar in both groups and did not change during peak pacing (Fig. 4). The LVEDP and PCW at rest in the patients without chest pain (11 ± 3 and 7 ± 3 mm Hg, respectively, Fig. 5) were essentially unchanged after pacing (12 ± 4 and 9 ± 3 mm Hg). In contrast, although the LVEDP and PCW were similar at rest (9 ± 5 and 7 ± 4 mm Hg, respectively), those patients having chest pain during pacing had a significant increase in LVEDP (14 ± 5 mm Hg, p <0.001) and PCW (11 ± 5 mm Hg, p <0.001) after pacing compared with rest measurements. In addition, the change in LVEDP from rest to postpacing was significantly greater in the chest pain group that the nonchest pain group (5 ± 2 versus 1 ± 2 mm Hg, p <0.001). No significant ST-segment depression or elevation was noted in any patient after pacing.

Ergonovine study: After a period of at least 20 minutes after the control study, repeat baseline mea-

	Yes	18	74 ± 15	8.9 ± 2.2	10.2 ± 3.7	102 ± 27†	13.1 ± 4.1	21.1 ± 3.3

* $p < 0.05$ versus control study GCV flow during pacing, no chest pain group.
† $p < 0.01$ versus ergonovine study GCV flow during pacing, no chest pain group.
GCV flow = great cardiac vein flow; HR = heart rate; $M\dot{V}O_2$ = anterior circulation oxygen consumption (ml O_2/min = AVO_2 diffference × GCV flow); SBP = systolic blood pressure.

surements were obtained. After administration of ergonovine, 0.15 mg intravenously, to 46 patients, 1 patient had chest pain before initiation of pacing and 30 other patients had their typical chest pain during subsequent pacing, including 13 patients who had no chest pain during the control study. Fifteen patients had no chest pain after ergonovine at rest, or during pacing, including 2 patients who had chest pain during the control study. There was no significant difference in baseline control values of HR, blood pressure, GCV flow or coronary resistance between the 2 groups (Table VI), nor was there significant change in these parameters from baseline values in the control study.

After administration of ergonovine, but before pacing, the group that subsequently had chest pain had a significant increase in coronary resistance and no change in GCV flow, whereas coronary resistance decreased and GCV flow increased in those never having chest pain after ergonovine (Fig. 6). The patient with chest pain before pacing (Patient 29) had the greatest increase in coronary resistance and decrease in GCV flow of any patient (Table VI). No ST-segment shift was observed on monitored leads in any patient.

During peak pacing after ergonovine administration, those patients having their typical chest pain had a lower absolute GCV flow (102 ± 28 versus 138 ± 31

p values determined comparing patients developing versus those not developing chest pain. * Atropine. † $p < 0.001$. Abbreviations as in Table IV.

ml/min, $p < 0.001$) and less of an increase in flow (38 ± 20% versus 107 ± 38%, $p < 0.001$) than those patients never having pain (Table VI, Fig. 2). Likewise, those patients having chest pain had a higher coronary resistance (1.22 ± 0.39 versus 0.84 ± 0.23 mm Hg/ml/min, $p < 0.001$), and less of a decrease in coronary resistance (−16 ± 12% versus −45 ± 11%, $p < 0.001$) compared with those patients never having chest pain. None of the 10 patients (Table IV) believed prospectively to have noncardiac pain had their typical chest pain during the ergonovine study.

Lactate consumption during peak pacing (Fig. 3) was significantly less in those patients having chest pain (39.2 ± 23.6 versus 65.3 ± 46.3 mM·ml/min, $p < 0.01$) compared with those patients without chest pain. AVO_2 difference decreased slightly (12.1 ± 0.9 at rest to 11.6 ± 1.1 ml O_2/100 ml during pacing, not significant) in those patients without pain (Fig. 4). In contrast, AVO_2 difference widened significantly (12.2 ± 1.1 at rest to 12.5 ± 1.3 ml O_2/100 ml during pacing, $p < 0.025$) in those patients with chest pain after ergonovine. During peak pacing, those patients having pain had a greater AVO_2 difference compared with those patients without pain (12.5 ± 1.3 versus 11.6 ± 1.0 ml O_2/100 ml, $p < 0.05$). Despite the significant difference in GCV flow between the 2 groups during maximal pacing, the pressure-rate product and $M\dot{V}O_2$ were not significantly different between the 2 groups (Table V).

The CI increased significantly during peak pacing after ergonovine in the group without chest pain (2.8 ± 0.3 at rest to 3.4 ± 0.7 liters/min/m^2 during pacing, $p < 0.001$) (Fig. 4) but was unchanged in the group with chest pain. After pacing, the LVEDP and PCW were significantly higher in the chest-pain group (19 ± 4 mm Hg, $p < 0.001$, and 16 ± 4 mm Hg, respectively, $p < 0.001$) (Fig. 5) compared with the no-chest-pain group (13 ± 2 and 11 ± 2 mm Hg). The increase in LVEDP (11 ± 3 versus 5 ± 2 mm Hg, $p < 0.001$) and PCW (9 ± 3 versus 4 ± 2 mm Hg, $p < 0.001$) from rest to postpacing was likewise significantly greater in the chest-pain group. Significant ST-segment depression (≥1 mm) after pacing was noted in 2 patients having chest pain.

Selective coronary arteriography performed immediately after pacing (approximately 4 minutes after ergonovine administration) showed no focal spasm and only minimal epicardial coronary artery luminal narrowing (−5 ± 7% proximal, −6 ± 9% mid, −4 ± 11% distal left anterior descending) compared with control arteriograms. Further administration of ergonovine in the majority of patients up to a cumulative dose of 0.4 mg produced <20% epicardial artery narrowing and no focal spasm.

Dynamic coronary vasoconstriction: Thirty-one patients had their typical chest discomfort during the ergonovine study, including 13 patients who had no chest pain during the control pacing study. Vasoconstriction of the coronary microcirculation was suggested by several observations. First, coronary resistance actually increased and GCV flow decreased in the patient having chest pain at rest after ergonovine infusion; these changes were the largest of any patient in the study and occurred without significant epicardial coronary artery luminal narrowing. In the remaining 30 patients with chest pain, coronary resistance increased significantly after ergonovine administration without epicardial coronary artery vasoconstriction, whereas it actually decreased in those patients never having chest pain. Second, during pacing at a HR of 150 beats/min, coronary resistance was higher (1.04 ± 0.34 mm Hg/ml/min, control study versus 1.22 ± 0.40 mm Hg/ml/min, erogonovine study, $p < 0.001$) and GCV flow was lower (111 ± 27 ml/min, control study versus 102 ± 28 ml/min, ergonovine study, $p < 0.001$) during ergonovine infusion in the 31 patients having chest pain, when compared with the control study at the same paced HR. This increase in resistance could not be ascribed to autoregulatory mechanisms responding to a lower $M\dot{V}O_2$, as the systolic blood pressure and HR product, an index of $M\dot{V}O_2$, was actually higher at maximal HR during the

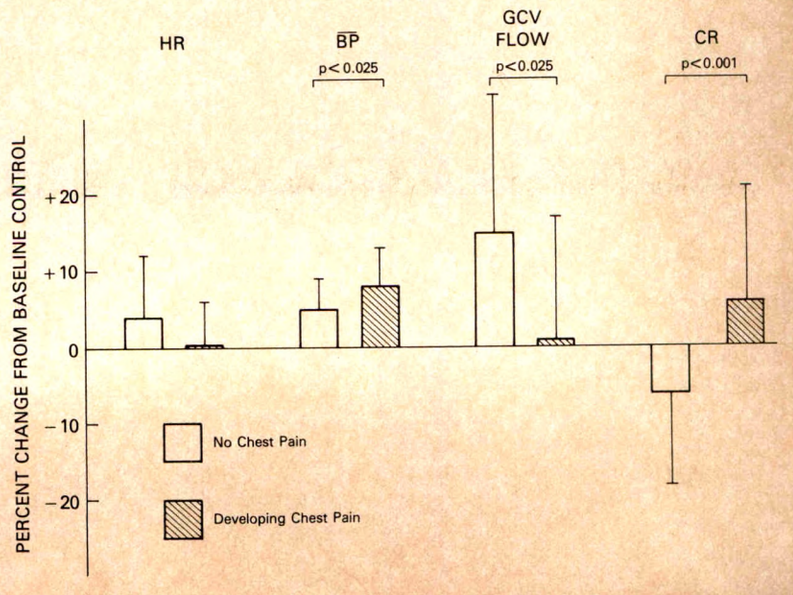

FIGURE 6. Percent change from baseline control after administration of ergonovine in heart rate (HR), mean blood pressure (BP), great cardiac vein (GCV) flow and coronary resistance (CR).

ergonovine study ($19.6 \pm 3.6 \times 10^3$, control study versus $20.6 \pm 3.3 \times 10^3$, ergonovine study, $p < 0.001$). This was confirmed by direct measurements of $M\dot{V}O_2$ in a subgroup of patients having chest pain after ergonovine: $M\dot{V}O_2$ was not lower at maximal paced HR during the ergonovine study (13.5 ± 3.7 ml O_2/min during control pacing versus 13.1 ± 4.1 ml O_2/min, not significant). Because coronary resistance actually increased in this group of patients, it appears that the changes we observed were due to an ergonovine-induced coronary vasoconstrictor response. That vasoconstrictor stimuli overrode autoregulatory influences is suggested by the fact that constriction occurred not only in the face of an increase in oxygen demand, but during myocardial ischemia, as evidenced by abnormal lactate metabolism, widening of the AVO_2 difference and elevation of the postpacing LVEDP.

Discussion

This study demonstrates that the chest pain had by many patients previously considered to have "normal" coronary arteries, and therefore noncardiac chest pain, may in fact be due to myocardial ischemia induced by abnormalities of the coronary microcirculation or arteries too small to be imaged by current arteriographic techniques. That the chest pain is ischemic in origin is suggested by several findings. When patients had their chest pain during pacing, a limitation in coronary blood flow increase occurred similar to that found in patients with obstructive coronary artery disease.[14] The pain and abnormal flow responses were associated with diminished lactate consumption and elevated postpacing LVEDP. These changes are characteristic of an ischemic response, reflecting alterations in aerobic metabolism[16,17] and ventricular compliance.[18] That the abnormal flow and resistance changes are due to inappropriate vasodilator reserve, or constriction of small coronary arteries or arterioles, is indicated by the fact that no significant alterations in epicardial coronary artery caliber were noted that could explain the increased resistance and inadequate flow responses.

The evidence favoring the concept that the abnormal vasodilator reserve exhibited by our patients produces myocardial ischemia must be critically assessed, because we are ascribing to ischemia the basic pathophysiologic mechanism responsible for the clinical syndrome presented by these patients. In this regard, although the decreased lactate consumption observed during pacing is less convincing evidence of ischemia than frank lactate production, the decrease in consumption probably represents a point on the spectrum of lactate metabolism ranging from appropriate increases in lactate consumption in response to increases in $M\dot{V}O_2$, to ischemia-induced lactate production.[16,17] Assessment of lactate metabolism from myocardial venous drainage also necessarily introduces sampling errors if the myocardium is not uniformly ischemic.[17] If the abnormal microcirculatory responses to pacing and ergonovine are diffuse or "patchy" in distribution, or primarily endocardial versus epicardial in location, the regional venous drainage may convey an admixture of normal and abnormal lactate responses, especially if the overall mass of ischemic myocardium is small. In addition, the sensitivity of lactate production assessment in detecting ischemia even in patients with significant obstructive coronary artery disease is modest at best.[19]

In contrast to the ischemic responses observed in the patients having chest pain, those patients not having chest pain during the control study achieved higher coronary blood flow responses to pacing, increased their lactate consumption, and had only minimal increases in LVEDP. The higher flow could not be ascribed to greater oxygen demands, as both the systolic blood pressure-HR product, an estimate of $M\dot{V}O_2$, and directly measured $M\dot{V}O_2$, were comparable to the values measured in patients with chest pain.

Further evidence favoring the concept that the chest pain our patients had was due to myocardial ischemia is suggested by our recent study, using radionuclide gated blood-pool imaging, which demonstrated that three quarters of our patients with abnormal vasodilator reserve had abnormalities of left ventricular function, either at rest or during exercise.[20]

Ergonovine infusion resulted in several interesting observations. First, 1 patient (Patient 29) had chest pain at rest associated with the greatest decrease in GCV flow and increase in coronary resistance of any patient in the study, and in another patient (Patient 43) coronary resistance actually increased during subsequent pacing, a change that was not accompanied by significant changes in epicardial coronary artery luminal diameter. Second, as a group, coronary resistance at rest actually increased in response to ergonovine in those patients who would have their typical pain during subsequent pacing. This was just the opposite of the appropriate response to the ergonovine-induced increase in arterial pressure, as exhibited by those patients never having pain in the ergonovine study—a decrease in coronary resistance and increase in GCV flow.

Although other studies have also suggested that some patients with chest pain and normal epicardial coronary arteries may have an abnormal small vessel response to ergonovine,[21–23] no data were obtained during hemodynamic stress and ischemia was not documented. This is extremely important from a pathophysiologic point of view. Thus, we found that when compared with the results of pacing in the control study, exacerbation of flow and resistance abnormalities occurred in those patients in whom pacing and ergonovine infusion actually resulted in chest pain (with associated metabolic and hemodynamic findings compatible with ischemia). Additionally, ergonovine and pacing precipitated an ischemic response in 13 patients who had a normal response to pacing during the control study. Normally, coronary arterioles act as the primary regulators of coronary blood flow; they dilate as myocardial oxygen demands increase so as to tightly couple myocardial oxygen supply and demand. In the patients with chest pain in this study, autoregulation of coronary blood flow was abnormal, such that vasoconstriction or inadequate vasodilation occurred even in the presence of myocardial ischemia. The abnormality appears to be dynamic, in that vasoconstrictor stimuli unmask or exacerbate this condition, a finding that may explain the mecha-

nism of resting and exertional chest pain with variation in anginal threshold, which was a clinical feature usually noted in these patients.

Limitations of study: The present study contained no true asymptomatic control subjects (normal volunteers), because in our judgment ethical considerations prohibited participation of such a population in an extensive invasive study that carried a risk of morbidity and mortality, albeit small. Thus it can be argued that the true "normal" response to pacing, with or without ergonovine, is unknown. Of course, similar objections apply to virtually all studies published to date in which patients with arteriographically normal coronary arteries served as control subjects. These patients have generally undergone arteriography because of chest pain syndromes and therefore are probably more like our subjects, rather than true "normals." Nevertheless, the coronary circulatory response to pacing and vasoconstrictor stimuli exhibited by patients having their typical chest pain during pacing clearly differed from that exhibited by patients not having pain during the study. In addition, none of 10 patients we prospectively suspected as having a noncardiac origin for their chest pain had chest pain or limitation to coronary blood flow during either the control or ergonovine studies. Thus, we believe the patients not having chest pain are a reasonable control group.

The absence of ST-segment depression during pacing-induced chest pain may reflect either a patchy, diffuse distribution of abnormal small vessels, or a nonhomogenous response to pacing or to vasoconstrictor stimuli. Additionally, if a diffuse distribution of myocardial ischemia exists, it might result in a cancellation of electrical forces, thereby accounting for the lack of ST-segment shifts observed during induced ischemia. Similar reasoning may explain the absence of ST depression during exercise testing in most of these patients, despite limitation by chest pain.

Causes of abnormal vasodilator reserve: Whether the microcirculatory abnormalities demonstrated in these patients is an expression of "small vessel spasm" and represents 1 end of the spectrum of coronary vasospastic phenomenon, or reflects morphologic small-vessel disease as has been reported in diabetes[24,25] and other diseases,[25] is unknown. Opherk et al[26] found that a group of patients with chest pain, abnormal exercise stress testing and normal epicardial coronary arteries had a limited pharmacologic vasodilator reserve after dipyridamole infusion compared with patients with atypical and presumably noncardiac chest pain. Endocardial biopsies performed in a subset of these patients revealed only minor mitochondrial abnormalities, although the small arteries we are concerned with—in the 100 to 300 μm range—cannot be adequately sampled by this technique. Another possible cause for the abnormalities demonstrated in our patients would be an underlying cardiomyopathic process with increase in diastolic filling pressures that would adversely affect myocardial blood flow.[27] However, the resting ventricular function by contrast ventriculography and LVEDP in most patients in this study were normal.

A recent report by Opherk et al[28] demonstrated limited pharmacologic vasodilator reserve after dipyridamole infusion in patients with longstanding hypertension and left ventricular hypertrophy on electrocardiography. Thirteen patients in our study were hypertensive by history (none had left ventricular hypertrophy on electrocardiography). Of these, 8 had chest pain during the control study and an additional 2 had chest pain during the ergonovine study. In addition to these 10, 3 patients without a history of hypertension had a mean arterial blood pressure $\geq$110 mm Hg in the catheterization laboratory: each subject had chest pain during the control or ergonovine studies or both. Of these 13 hypertensive patients with pacing-induced chest pain, 10 had an increase in coronary resistance and a decrease in GCV flow after ergonovine administration in a manner identical to the 18 normotensive patients with chest pain after ergonovine. Thus, the majority of patients with hypertension in our study who had chest pain appeared to have dynamic abnormalities of the coronary microcirculation.

The prevalence of myocardial ischemia as the cause of the chest pain in subjects with "normal" coronary arteries is unknown. Based on our experience, however, we suspect it is not uncommon in patients who have the type of pain patterns an experienced clinician believes include many of the characteristics of myocarcdial ischemia.

The question naturally arises as to how patients with abnormal vasodilator reserve can be identified, since electrocardiographic exercise studies are usually negative and the coronary tone study we performed for investigational purposes cannot be considered a practical diagnostic approach for routine clinical use. Radionuclide testing may offer a noninvasive solution to this dilemma, as most patients considered to have small-vessel abnormalities in this study also had abnormal ejection fraction responses or wall motion abnormalities during exercise.[20]

Therapeutic interventions must usually be considered, as these patients often have incapacitating chest pain. Nitrates seem to be effective in controlling symptoms in some patients, but most of the patients referred to the National Institutes of Health have been refractory to usual antianginal medications. Recent studies we have performed suggest that calcium-channel blockers control chest pain very effectively in patients with this syndrome, probably as a result of their potent arteriolar vasodilating properties.[29]

The prognosis of patients with chest pain and normal coronary arteries has been considered to be benign.[30,31] However, patients often continue to have significant and debilitating chest pain despite repeated reassurance.[32] Moreover, in the subgroup of such patients with documented abnormal coronary tone, we have found that 17% had regional wall abnormalities at rest, often associated with reduced global ejection fraction. These latter findings suggest that myocardial necrosis can occur in these subjects in the absence of abnormalities of the epicardial coronary arteries. Hence, the ultimate prognosis of those patients who have myocardial ischemia as the basis for their chest pain may not be so

benign; however, long-term follow-up studies will be required to define the natural history of this interesting condition.

Dynamic Coronary Obstruction as a Cause of Angina Pectoris: Implications Regarding Therapy

STEPHEN E. EPSTEIN, MD, RICHARD O. CANNON III, MD, RITA M. WATSON, MD, MARTIN B. LEON, MD, ROBERT O. BONOW, MD, and DOUGLAS R. ROSING, MD

The strong link demonstrated at autopsy between coronary atherosclerosis and angina pectoris led to the important concept that a fixed obstruction of 1 or more coronary arteries was the pathophysiologic cause of angina: myocardial ischemia and angina occurred when myocardial oxygen demand outstripped the capacity of the diseased coronary artery to deliver oxygen. Therapeutic strategies were based on attempts to lower myocardial oxygen needs induced by physical and emotional stress. However, the finding that dynamic increases in coronary vascular resistance can also either precipitate ischemia or reduce the threshold of myocardial oxygen consumption ($M\dot{V}O_2$) at which it occurs has profoundly altered our understanding of the pathophysiologic features of angina and, therefore, its treatment. Dynamic coronary obstruction can occur at the large-vessel level, causing Prinzmetal's or variant angina. It is also possible that in some patients a continuum of large-vessel coronary vasoconstrictor tone exists, causing the common clinical situation manifested by angina with variable thresholds of onset. Recent studies have demonstrated that increases in the resistance offered to flow by small coronary arteries too small to be imaged by angiography can also decrease anginal threshold. The fact that ischemia can be precipitated by dynamic increases in large- or small-vessel coronary resistance has important implications for the therapy of angina pectoris. In those persons who mostly have a dynamic component contributing to their coronary obstruction, primary intervention with vasodilator therapy, including nitrates and calcium-channel blocking agents, are probably most effective therapeutically. In those persons with fixed obstruction and little evidence of a dynamic component, the traditional therapeutic approach designed to reduce myocardial oxygen consumption would be most efficacious. This would include the use of nitrates and β blockers. On the other hand, those persons who have a combination of fixed and dynamic obstruction might benefit either from interventions designed either to lower $M\dot{V}O_2$ or to relieve obstruction; some patients might require both approaches for optimal symptomatic control. The recognition that dynamic influences can profoundly exacerbate the degree of coronary obstruction at either the large- or small-vessel level should influence medical approaches to the alleviation of ischemic pain and result in more effective treatment of anginal syndromes.

(Am J Cardiol 1985;55:61B–68B)

Over 40 years ago, a strong link was demonstrated between the coronary atherosclerosis observed at autopsy and the clinical syndrome of angina pectoris.[1] Since that time, the belief has evolved that angina is due to fixed obstructions that limit the capacity of the coronary artery to augment flow in response to increased metabolic demands: angina occurs when a threshold—beyond which further increments in oxygen delivery can no longer be achieved—is reached. In the past decade, however, 2 important developments have effectively refuted the concept that fixed stenosis can entirely account for the diverse clinical syndromes characterized by angina. The first major challenge was the demonstration that large-vessel coronary spasm is the major cause of Prinzmetal's or variant angina.[2–5] This seminal observation totally altered our understanding of the pathophysiologic make-up of angina; it introduced the concept that *dynamic* increases in large-vessel coronary obstruction might occur that could precipitate ischemic symptoms. The second major challenge to the primacy of fixed large-vessel obstruction as the sole cause of angina in patients with ischemic heart disease was the very recent demonstration that abnormal vasocon-

strictor influences affecting the *small* coronary arteries can precipitate both rest and exertional angina, even in the absence of large-vessel obstructive disease.[6]

The recognition that dynamic increases in either large- or small-vessel coronary resistance can precipitate or exacerbate angina has profoundly altered our approach to the treatment of angina pectoris. In this article we review the concept of dynamic coronary obstruction and outline its impact on our therapeutic approach to the patient with angina.

Normal Mechanisms Controlling Coronary Flow

The normal coronary system consists of large epicardial vessels, which normally function largely as passive conduits and offer little intrinsic resistance to flow (R_1, Fig. 1). The intramyocardial arterioles, on the other hand, alter their intrinsic tone in response to the demands of the myocardium for oxygen. Because of their small diameter and well-developed media, they have the capacity to alter resistance to flow profoundly (R_2, Fig. 1). Because flow is inversely related to resistance (and directly related to driving pressure), this analysis indicates that myocardial flow is inversely related to R_2. Through the autoregulatory system provided by the arterioles, myocardial oxygen delivery and myocardial oxygen consumption ($M\dot{V}O_2$) are tightly coupled: when $M\dot{V}O_2$ increases the resistance vessels dilate and thereby permit myocardial flow to increase in proportion to the increased oxygen demands.

When a large epicardial vessel is narrowed by an atherosclerotic lesion, its conductance function is compromised and it now offers considerable resistance to flow. If no other alteration occurs, the increased resistance leads to a decrease in flow and thereby causes ischemia. However, ischemia-induced metabolic derangements activate autoregulatory mechanisms, resulting in arteriolar dilatation and decrease in R_2. Because R_1 and R_2 (Fig. 1) are in series, total coronary vascular resistance returns toward normal. Further increases in large vessel obstruction cause progressive arteriolar dilatation, and resting flow will remain normal until the vasodilator reserve of the arterioles is exceeded.

Although this compensatory mechanism may prevent the appearance of ischemia under resting conditions, it is not adequate to prevent ischemia when large increments in flow are required, as with exercise. During exercise, once the vasodilator reserve of the arterioles is exhausted, flow can no longer increase as a result of further decreases in resistance. When this maximal flow threshold is exceeded, myocardial ischemia and angina appear.

Dynamic Coronary Obstruction

Although the concept of fixed obstruction provides a ready explanation for the onset of angina with exercise when $M\dot{V}O_2$ increases considerably, it cannot explain the onset of angina occurring at rest without obvious increase in $M\dot{V}O_2$. This implies that resting flow diminishes and, therefore, that resistance to flow must increase. The concept of fixed obstruction also does not explain why anginal threshold should vary markedly during different times of the day, different times of the week or different seasons of the year, as it so frequently does in patients with angina. For example, patients often report that in the morning relatively mild activities precipitate angina, but as the day progresses the same activities can be undertaken without pain.

Large-vessel spasm: The pioneering studies of Maseri,[7] Oliva[8] and their co-workers demonstrated that large-vessel spasm can decrease flow in a "normal" coronary artery or one narrowed by atherosclerotic plaque, and thereby precipitate transient episodes of angina at rest.[2–4] Additional studies have suggested that spasm-induced decrease in myocardial blood flow is not only responsible for variant angina, but can lead to unstable angina, myocardial infarction and sudden death.[3,4,8] These observations have been of critical importance in understanding the mechanisms contributing to the precipitation of angina. However, although the concept of spasm could be invoked to account for the previously unexplained appearance of pain at rest, the cause of the often marked variations in exertional anginal threshold remained unexplained.

The demonstration that angina occurring during exercise, particularly if associated with ST-segment elevation, was on occasion associated with exercise-induced narrowing of large coronary arteries,[9,10] offered one explanation for the marked variations in exercise capacity in many patients with angina.

It was subsequently suggested that variable threshold angina might also be caused by more subtle vasoconstrictor influences playing on the large coronary arteries that, although not causing total or near total coronary obstruction at rest, was severe enough to interfere with the normal augmentation of flow that occurs with exercise.[11] Thus, the concept of coronary spasm was broadened. At one end of the spectrum is spasm so severe that it causes total or near-total coronary obstruction and results in pain at rest. At an intermediate point of the spectrum, we might find mild large-vessel coronary vasoconstriction leading to a diminished threshold of exercise-induced angina. At the other end

TABLE I Strategy for Treating Angina Pectoris Dependent on Presence or Absence of Dynamic Coronary Constriction

of the spectrum, coronary tone might actually diminish, with the resulting vasodilation leading to improved exercise capacity.

How resistance to flow can be profoundly altered by small changes in large-vessel coronary diameter can be appreciated by considering some simplified hydrodynamic principles. For example, Poiseuille's law states: $Q = (\pi r^4/8\mu) \times (\Delta P/L)$ where Q = flow, r = the radius of the vessel, μ = the viscosity of blood, ΔP = the driving pressure across the coronary bed and L = the length of the vessel or obstructing lesion. Because $R = \Delta P/Q$, then $R = 8\mu L/\pi r^4 = 8(0.04) \times 16 \times L/\pi D^4 = 1.63 \times L/D^4$ where R = resistance to flow and D = the diameter of the vessel. Thus, resistance to flow is directly proportional to the length of the lesion or vessel, but most importantly is inversely proportional to the fourth power of the vessel diameter.

These concepts are graphically illustrated in Figure 2. The epicardial coronary artery, the diameter of which averages about 3 mm, offers little resistance to flow under normal situations; the major resistance to flow occurs in the small arterioles or resistance vessels. However, relatively small dynamic changes in vascular tone involving the large epicardial coronary vessels might have a profound impact on coronary resistance (and hence, flow) if either a preexisting lesion narrowed the vessel even to a "subcritical" degree, or if the increased tone, producing only a moderate decrease in vessel diameter, involved the entire length of the epicardial vessel (because resistance is also directly proportional to its length).

Changes in vasoconstrictor influences playing upon the large epicardial coronary vessels undoubtedly account on occasion for the varying thresholds of exertional angina seen in many patients. However, we have noticed that patients referred to us with variable threshold angina, especially those who had no ST-segment shifts in their electrocardiogram (ECG) during episodes of pain, rarely had large-vessel coronary spasm in response to such vasoconstrictor maneuvers as ergonovine or cold pressor testing.[6] This contrasted with the high frequency of spasm demonstrated in patients with pain at rest who had concurrent shifts in ST-segments of the ECG.[12]

Small coronary artery vasoconstriction and decreased vasodilator reserve: Our observation that standard ergonovine testing usually failed to precipitate coronary artery spasm in patients with variable threshold angina prompted us to measure regional coronary blood flow and resistance in these patients to determine whether their pain might be due to constriction of coronary vessels too small to be imaged by angiography.[6] Although in this study most patients had a component of pain at rest, patients with classic Prinzmetal's angina were excluded by requiring that when ECGs were obtained during episodes of pain no ST-segment shifts were manifested. Patients with significant large-vessel disease were specifically excluded to avoid the inaccuracies inherent in measuring small changes in the caliber of stenotic vessels which, despite the small magnitude of change, could lead to major alterations in coronary vascular resistance (Fig. 2). Great cardiac vein flow was measured by a thermodilution catheter introduced into the coronary sinus and advanced to the great cardiac vein. This vessel drains approximately 90% of the blood flowing through the left anterior descending coronary artery. The protocol involved increasing $M\dot{V}O_2$ by pacing the heart up to rates of 130 to 150 beats/min under control conditions, during cold pressor testing (for which the patient's hand was immersed to the wrist in ice water during the course of the pacing) and during ergonovine infusion (0.15 mg

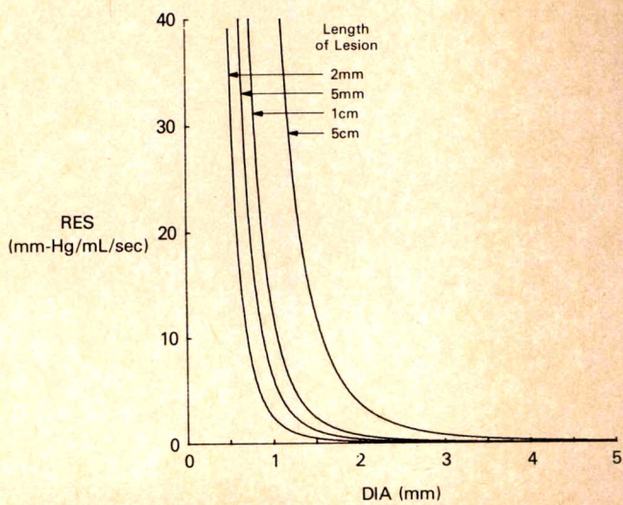

FIGURE 2. Relation between coronary arterial diameter (DIA) and resistance (RES) to flow. Obstructive lesions of different lengths are described by 4 different curves; as length of lesion increases, resistance to flow increases at any given vessel diameter. However, because resistance is inversely proportional to the fourth power of vessel diameter, vessel diameter is the preponderant influence on resistance to flow. administered intravenously).

When the coronary flow and resistance responses were analyzed, persons without chest pain during pacing had large decreases in coronary resistance and increases in great cardiac vein flow. In contrast, these responses were markedly attenuated in those patients in whom pain developed (Fig. 3). Ergonovine infusion resulted in the greatest number of abnormal responses: 2 patients actually had pain at rest during the intervention, which was associated with marked diminutions in coronary flow and increases in resistance. Differences in lactate metabolism between the 2 groups were consistent with the conclusion that the chest pain experienced by the patients with small changes in coronary flow and resistance was indeed due to myocardial ischemia. The fact that the diameter of the large coronary arteries was essentially unaltered with pacing and during vasoconstrictor maneuvers is very important. It indicates that the site at which the abnormal vasodilator reserve or actual constriction occurred was in coronary arteries too small to be imaged angiographically.

Hence, these data provide compelling evidence that abnormalities at the level of the small coronary arteries can contribute to precipitation of myocardial ischemia, either by dynamically increasing coronary resistance in response to vasoconstrictor influences profound enough to cause ischemia at rest, or by restricting vasodilator reserve and thus the potential to augment flow, which would predispose to the development of ischemia during interventions or activities that increase myocardial oxygen requirements.

Although the abnormal coronary vasodilator reserve we demonstrated can be ascribed to vasoconstrictor influences modulating the tone of small coronary arteries,[13–20] our results do not allow us to rule out the possibility that the inadequate vasodilator reserve could be due to abnormal myocardial compressive forces. Thus, a primary abnormality in myocardial relaxation leading to a retardation in the rate of early diastolic relaxation, or the presence of an occult cardiomyopathy

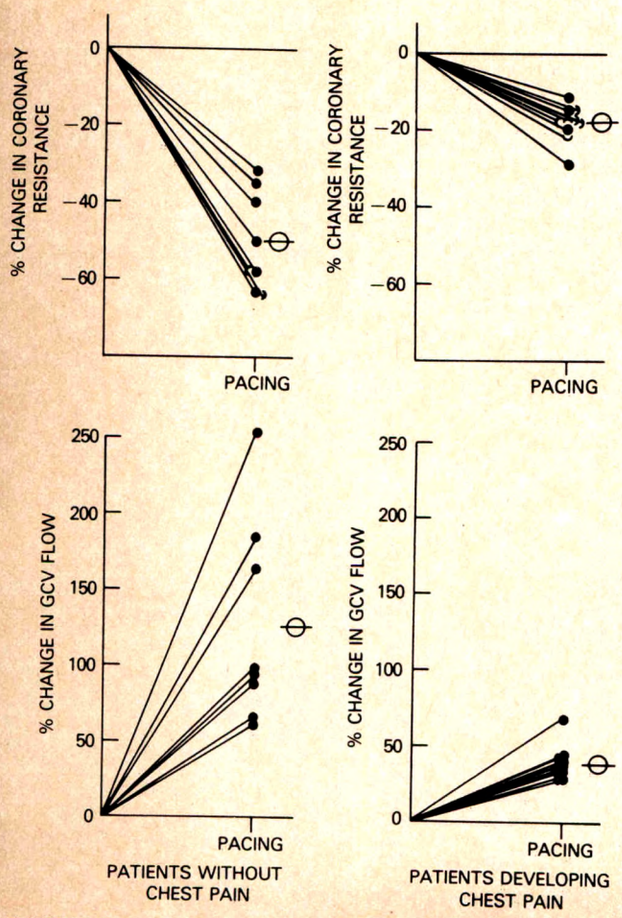

FIGURE 3. Percent change in coronary resistance (calculated from great cardiac vein [GCV] flow and mean arterial pressure) and flow in response to pacing from baseline control heart rate to heart rates of 130 to 150 beats/min. These results were obtained during infusion of ergonovine (0.15 mg intravenously).

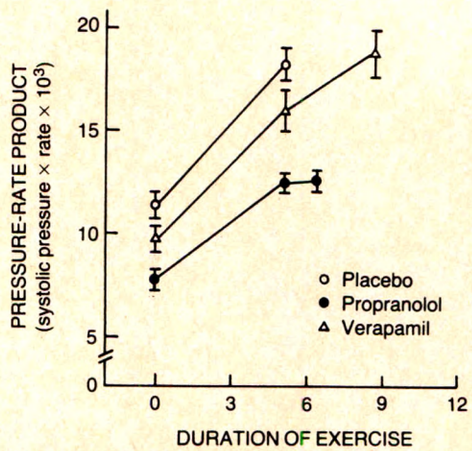

FIGURE 4. Double product (heart rate × systolic pressure) response to exercise of patients under control conditions (**open circles**), during oral verapamil administration (**open triangles**) and during oral propranolol administration (**closed circles**). Exercise intensity was increased by 20 W every 3 minutes. Patients stopped at a symptom-limited endpoint.

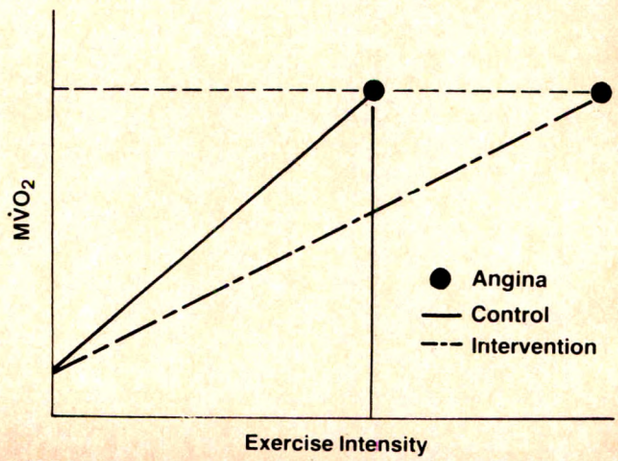

FIGURE 5. Diagrammatic representation of results after intervention that improves exercise capacity by diminishing myocardial oxygen consumption ($M\dot{V}O_2$). With such an intervention, exercise capacity improves but angina occurs at same or lower level of $M\dot{V}O_2$.

leading to increased left ventricular filling pressure, might increase myocardial wall tension during diastole and thereby interfere with coronary flow.[21] It is also possible that the mechanisms responsible for this syndrome are multiple, and that although some persons may have angina as a result of increased vasoconstrictor influences exerted on small coronary arteries, others may have abnormalities of myocardial relaxation or undetected cardiomyopathy.

Effects of Calcium-Channel Blockers on Exercise Responses

Possible effects on myocardial flow: The fact that ischemia can be precipitated by dynamic increases in large or small vessel coronary resistance raises interesting questions regarding the mechanism by which calcium-channel blockers improve exercise capacity in patients with coronary artery disease.[22–33] Although several studies have attempted to elucidate the mechanisms responsible for this salutary effect, definitive data are lacking. However, some insights might be derived by analyzing the results of a randomized double-blind study in which we assessed the effects of verapamil and propranolol on exercise capacity and the circulatory response to exercise.[29] Eleven patients were selected for study who had clinically failed traditional medical therapy, including β blockers and nitrates; several had had unsuccessful coronary bypass surgery. Exercise capacity improved with verapamil when compared with the results attained with either placebo or clinically determined "best dose" of propranolol. In an attempt to determine the possible mechanism of action of verapamil's beneficial effect, we compared the effects of the drugs on the product of systolic pressure and heart rate (double product), an indirect index of myocardial oxygen demand. We found that propranolol, as expected, markedly decreased the double product both at rest and during exercise. The double product also tended to be lower with verapamil. However, although verapamil improved exercise capacity to a significantly greater degree than did propranolol, its double product lowering action was far less (Fig. 4). These findings suggest that although a decrease in $M\dot{V}O_2$ might contribute to the beneficial clinical effects of verapamil, other mechanisms are also probably operative.

This conclusion was reinforced by examining the double product achieved by each of the patients at the time of angina onset. The double product at angina onset is a reflection of the maximal rate at which the obstructed coronary artery is capable of delivering oxygen. If an intervention improves exercise capacity, but the double product at angina is no higher than control levels, it implies that the intervention causes the beneficial effect by decreasing oxygen demands at any level of external stress (Fig. 5). If exercise capacity is improved and double product at angina increases, it implies that the myocardium can attain a higher workload before ischemia occurs, most likely because myocardial flow has increased (Fig. 6).

Figure 7 displays the double product attained at angina onset during placebo and verapamil studies. The double product response to verapamil is markedly heterogeneous; verapamil is associated with the attainment of considerably higher double product levels in 3 patients and in somewhat higher levels in another 3. The remaining patients had either no change or a decrease in the double product at the end of exercise.

These data can be interpretated as demonstrating merely that the double product response to exercise is not reproducible. Alternatively, if only the mean data

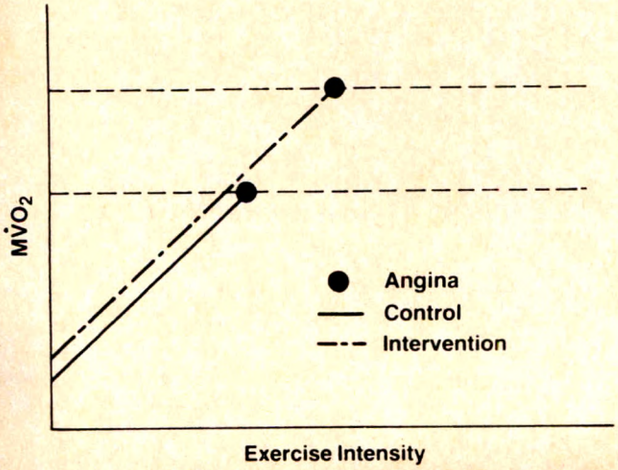

FIGURE 6. Diagrammatic representation of findings after intervention that improves exercise capacity consequent to improvement in myocardial oxygen delivery. Exercise capacity improves and patient is able to exercise to a higher level of myocardial oxygen consumption ($M\dot{V}O_2$) before stopping from angina.

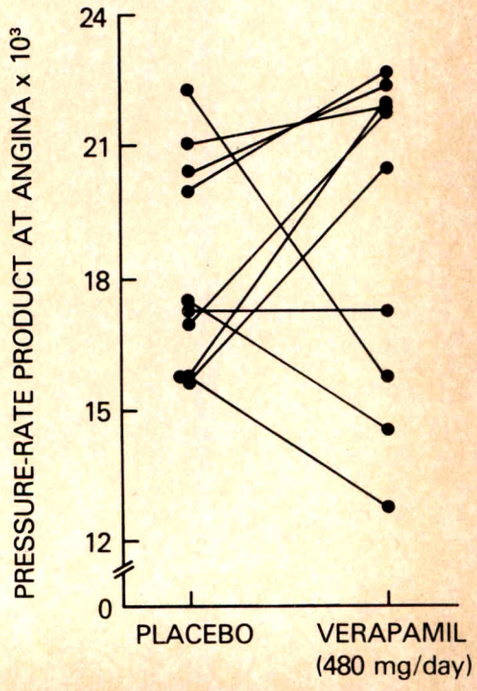

FIGURE 7. Double product at onset of angina under placebo conditions and during long-term administration of oral verapamil. Patients performed exercise on bicycle in upright position and verapamil or placebo was administered in randomized double-blind trial. Reproduced with permission from *Am J Cardiol.*[11]

are examined, it can be concluded that verapamil does not result in the myocardium attaining a higher level of oxygen consumption before the onset of ischemia. A third explanation, however, appears more compatible with the concepts of the pathogenesis of angina we have presented. The mechanisms responsible for the precipitation of angina are heterogeneous and undoubtedly vary considerably from 1 patient to another. Hence, the results depicted in Figure 7 may reflect variability in the mechanisms contributing to the precipitation of angina among the patients. Those patients in whom the double product increased at angina after verapamil administration may have had a dynamic component contributing to flow resistance; the improved exercise capacity produced by verapamil may have been at least partly the result of the drug dilating either the large[34,35] or small[36] coronary arteries, thereby increasing myocardial flow and oxygen delivery.

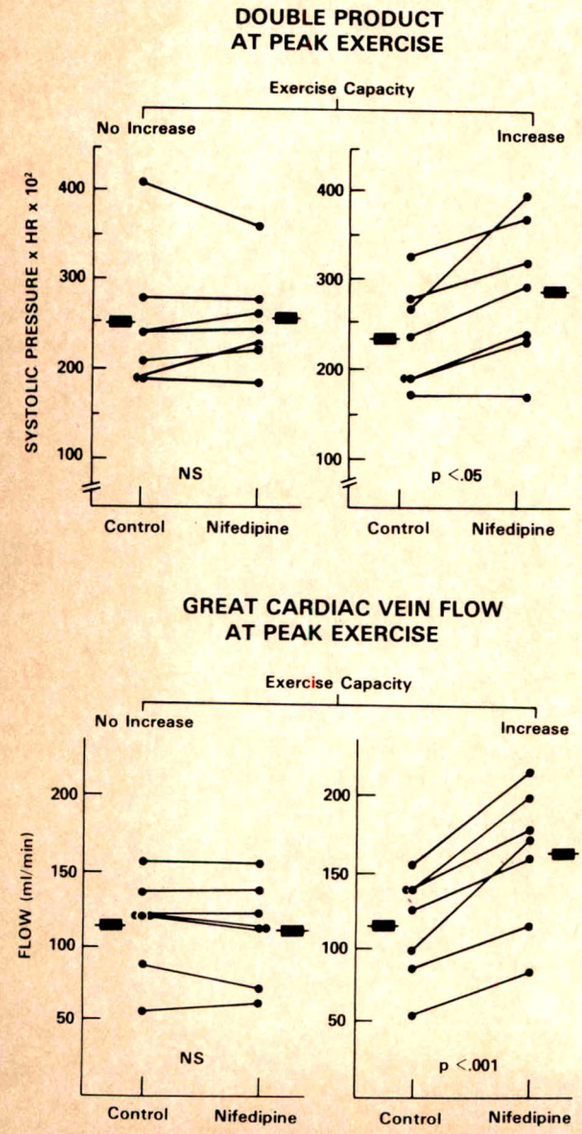

FIGURE 8. Circulatory effects of nifedipine in patients with angina, each of whom had stenosis of left anterior descending coronary artery derived from data by Specchia et al.[37]

This latter explanation is further substantiated by the results of a study examining the effects of nifedipine on both exercise capacity and hemodynamic response to exercise in a group of patients with angina, each of whom had stenosis of the left anterior descending artery.[37] Patients were studied during supine exercise in the catheterization laboratory. In addition to measuring heart rate and arterial pressure, the investigators introduced a flow catheter into the great cardiac vein through the coronary sinus. The great cardiac vein drains flow from the the left anterior descending coronary artery; hence, anterior regional coronary resistance could also be calculated. After nifedipine, exercise capacity showed no change in 7 patients and increased in another 7. The patients with unaltered exercise capacity failed to increase their double products and great cardiac vein flows at peak exercise after nifedipine. In contrast, the patients with improved exercise capacity increased double product and peak flow (Fig. 8). These changes were associated with a decrease in coronary vascular resistance. Zacca et al[38] found similar correlations. When administration of nifedipine improved exercise performance, the improvement was usually associated with an increased double product at peak exercise, as well as an increased left ventricular ejection fraction as determined by radionuclide angiography.[38] Hence, these results are compatible with the hypothesis that 1 of the mechanisms by which calcium-channel blockers improve exercise capacity in patients with angina caused by coronary artery disease is by dilating the coronary arterial system and thereby increasing flow to potentially ischemic regions. Whether the dilatation occurs in the region of the diseased portion of the epicardial vessel, in small coronary arteries or at the arteriolar level is unknown. It is likely that the locus of action varies from patient to patient, depending on the severity of stenosis and whether inadequate vasodilator reserve coexists with large-vessel atherosclerotic disease.

Possible effects on diastolic function: Another possible mechanism contributing to the improvement in symptoms produced by calcium-channel blockers may relate to their ability to improve diastolic function and to reduce inappropriate coronary vasoconstriction. The improvement in left ventricular rapid diastolic filling caused by verapamil[39] could contribute to the enhanced anginal threshold if improved filling reflects an increased rate of isovolumic relaxation, causing in turn an accelerated rate of decrease in myocardial wall tension at the onset of diastole. The resulting decrease in resistance to coronary flow, occurring at a time in the cardiac cycle when flow is usually greatest, would thereby augment myocardial blood flow. It should be pointed out, however, that there are differences in the capacity of the various calcium-channel blocking agents to alter diastolic function. Thus in 1 experimental study in which dose-response curves of verapamil, nifedipine and diltiazem were compared at doses producing equivalent decreases in arterial pressure or resistance, the greatest increase in early diastolic filling rate was

achieved by verapamil and the least by diltiazem.[40] It was also shown that changes in left ventricular filling pressures did not account for these differences.

Treatment Strategy: Concepts of Fixed and Dynamic Coronary Obstruction

Table I outlines the therapeutic approaches implicit in the concepts presented in this report regarding the pathophysiologic mechanisms responsible for the precipitation of angina pectoris. In the patient with variable threshold angina and normal coronary arteries, it can be inferred that coronary flow is impeded by dynamic factors and therefore that interventions designed to decrease coronary resistance and increase flow would appear most appropriate. This can probably best be achieved by the administration of nitrates, calcium-channel blocking agents or a combination of these 2 classes of agents. Administration of β-blocking compounds would probably be largely ineffective, and might even lead to dimunition in exercise performance. Such a paradoxical effect of noncardioselective β blockers was reported in patients with dynamic forms of coronary obstruction.[41–44] It might result from the drugs' capacity to block coronary β_2 (vasodilator)-adrenergic receptors, or from unopposed baroreceptor-mediated coronary vasoconstriction triggered by the blood pressure-lowering effects of the β blockers.

In patients with documented coronary artery disease and with a history of reproducible exertional angina and little or no pain at rest, it can be assumed that a fixed, or relatively fixed, coronary obstructive lesion is the major cause of ischemic symptoms. These persons would probably respond best to nitrates and β-adrenergic blocking drugs. If such patients' symptoms are refractory to this approach, a calcium antagonist can be added because these drugs do have some capacity to decrease $M\dot{V}O_2$.

Patients with a combination of fixed and dynamic obstruction probably constitute a relatively common subgroup of patients. These persons have symptoms of exertion-induced angina, which on superficial questioning may appear to develop at a fairly consistent level of stress. However, a carefully obtained history will usually reveal that the anginal threshold does vary and that episodes of angina at rest are either occasional or frequent. The approach to therapy in this subgroup of patients must be empirical, because it cannot be readily discerned clinically whether the predominant mechanism producing ischemia is related to the fixed or the dynamic component of obstruction. Some patients might respond best to attempts at decreasing myocardial oxygen consumption with the administration of nitrates and β-blocking agents. Others may respond to attempts at relieving the dynamic component of the increased coronary resistance with nitrates and calcium-channel blocking agents. Best results might be achieved in still other patients by combining nitrates, β blockers and calcium antagonists.

In summary, considerable information has accrued over the past few years that has helped to advance our understanding of the mechanisms responsible for precipitating or exacerbating anginal pain. Although atherosclerotic coronary obstructions are critically important in the precipitation of angina pectoris, the recognition that dynamic influences can profoundly alter the degree of coronary resistance at either the large- or small-vessel level will enable the physician to develop more effective medical approches to alleviate ischemic pain.

Combination Therapy with Calcium-Channel Blockers and Beta Blockers for Chronic Stable Angina Pectoris

MARTIN B. LEON, MD, DOUGLAS R. ROSING, MD, ROBERT O. BONOW, MD, and STEPHEN E. EPSTEIN, MD

Combination therapy using calcium-channel blockers and β blockers in patients with refractory chronic stable angina has gained much popularity, but remains highly controversial because of the potential for serious additive deleterious hemodynamic or electrophysiologic reactions. In studies involving patients with preserved left ventricular function receiving chronic oral β blockers, short-term administration of intravenous verapamil has been shown to cause a further lowering in heart rate and blood pressure while prolonging atrioventricular node conduction; additive cardiodepressant effects were noted, including a tendency toward increased left and right heart filling pressures. Nifedipine, on the other hand, when added acutely to β blockers, causes an increase in heart rate, a decrease in blood pressure and either no change or a slight improvement in most cardiac performance variables. Controlled, double-blind clinical trials have demonstrated that combinations of calcium-channel blockers and β blockers result in augmented symptom benefit compared with either drug class alone. The predominant mechanism responsible for such improvement is increased lowering of myocardial oxygen demand by virtue of additive diminution in heart rate, blood pressure and, consequently, pressure-rate product both at rest and during exercise. Verapamil (and possibly diltiazem) plus β blockers appears to have the greatest therapeutic efficacy but also the highest frequency of harmful adverse cardiac effects, whereas nifedipine plus β blockers is generally safer but also less efficacious. Factors that should be carefully considered by clinicians contemplating combination therapy are the choice of calcium-channel blocker, the dose of calcium-channel blocker and β blocker, the presence of antecedent left ventricular dysfunction or conduction system disease and the possibility of drug interactions.

Concomitant calcium-channel blocker and β-blocker therapy is an important contribution to the pharmacologic management of resistant patients who remain symptomatic during single drug treatment. However, the possibility of additive adverse cardiac effects mandates careful patient selection and close clinical monitoring.

(Am J Cardiol 1985;55:69B–80B)

A remarkable volume of clinical and basic investigation pertaining to calcium-channel blockers has dominated the medical literature over the past several years. As a group, these drugs have been demonstrated to be versatile and important cardioactive agents and have found specific application in all forms of ischemic chest pain syndromes (variant angina, unstable angina and chronic stable angina), systemic hypertension, supraventricular tachyarrhythmias and hypertrophic cardiomyopathy.

Verapamil, nifedipine and diltiazem have each been shown to be effective antianginal agents in patients with chronic stable angina. Multiple clinical trials have indicated that these drugs reduce episodes of angina, diminish nitroglycerin consumption, improve exercise performance and lessen ischemic electrocardiographic changes during exercise.[1–10] Previously, β-adrenergic blocking agents, alone and in combination with long-acting nitrate compounds, had been accepted as standard medical therapy in most patients with chronic stable angina. Now, with the broader use of calcium-channel blocking agents for ischemic chest pain, it is useful to consider the potential beneficial interactions between calcium-channel blockers and β blockers, as well as possible adverse drug-related effects.

TABLE I Comparative Effects of Calcium-Channel Blockers on Various Cardiovascular Functions

	Drug		
	Nifedipine	Verapamil	Diltiazem
Heart rate	↑	↓	↓↓
AV nodal conduction	0	↓↓↓	↓↓
Contractility	0	↓↓	↓
Vasodilation	↑↑↑	↑↑	↑
Diastolic filling	↑	↑↑	0

AV = atrioventricular.

Physiologic Considerations

Long before calcium-channel blockers and β blockers were combined in clinical practice, several theoretical concerns regarding combination therapy were raised. Calcium-channel blockers and β blockers have each been shown to reduce heart rate, depress atrioventricular (AV) nodal function, lower blood pressure and reduce myocardial contractility. Moreover, there is evidence to suggest that these groups of drugs induce electrophysiologic and hemodynamic effects by different underlying mechanisms of action.[11] Therefore, it was reasonable to assume that combination therapy might initiate additive and maladaptive changes that could manifest clinically as episodes of bradyarrhythmias, severe hypotension or congestive heart failure.

In contrast to β blockers, calcium-channel blockers represent a pharmacologically diverse and physiologically complex group of drugs. It bears emphasizing that the net hemodynamic effect of a given calcium-channel blocker is the composite of its direct or intrinsic pharmacologic properties and the resultant cardiovascular reflexes evoked (Fig. 1, left). Unfortunately, few clinical studies have examined the differences between calcium-channel blockers in the same patient cohort. Thus an accurate description of comparative cardiovascular effects at equipotent therapeutic dosages becomes problematic. Nevertheless, by extracting data from multiple clinical sources, several generalizations seem appropriate. Verapamil has negative chronotropic and inotropic properties, is a systemic and coronary vasodilator[12] and depresses AV nodal conduction (Table I). Verapamil also improves diastolic filling characteristics measured using both echocardiographic and radionuclide angiographic techniques.[13–15] Nifedipine, on the other hand, behaves predominantly as an arteriolar and possibly arterial vasodilator. In humans with an intact sympathetic nervous system, the hypotension caused by nifedipine elicits a profound reflex sympathetic response that tends to negate any intrinsic effect the drug may have on heart rate, AV nodal conduction and myocardial contractility (Table I). Nifedipine has been shown to improve diastolic filling properties in patients with hypertrophic cardiomyopathy, but to a lesser degree than verapamil.[16,17] Experimental studies in dogs with induced myocardial ischemia[18] have also shown that verapamil improves diastolic filling to a greater extent than nifedipine at doses of the drug that produce equivalent changes in arterial pressure. Diltiazem more closely resembles verapamil than nifedipine, and compared with verapamil seems to result in greater heart rate lowering effects with lesser influences on AV nodal conduction, myocardial contractility and vasodilation (Table I). Although no human data are available at present, preliminary observations derived from canine investigations suggest that diltiazem has little or no effect on diastolic filling behavior.[18]

When β-adrenergic blocking agents are added to calcium-channel blockers, the consequent blunting of reflex β-adrenergic responses constitutes a double-edged sword: it may enhance or unmask intrinsic drug properties that could result in either increased therapeutic efficacy or harmful adverse effects (Fig. 1, right). In patients with normal left ventricular (LV) function and no evidence of conduction system disease, combination therapy usually results in no serious adverse cardiac effects while increasing antianginal potency by virtue of an additive diminution in heart rate, blood pressure and, possibly, contractility, all of which serve to further decrease myocardial oxygen demands. However, the risk-benefit ratio associated with combination therapy may prove disadvantageous in patients with antecedent sinoatrial (SA) or AV nodal conduction system abnormalities who are prone to bradyarrhythmias, or in patients with clinically significant LV dysfunction. Combination β-blocker and calcium-channel blocker therapy may be especially hazardous in patients with congestive heart failure because such persons have little contractile reserve and often have depleted cardiac catecholamine stores, relying mainly on circulating catecholamines to maintain adequate cardiac compensation.

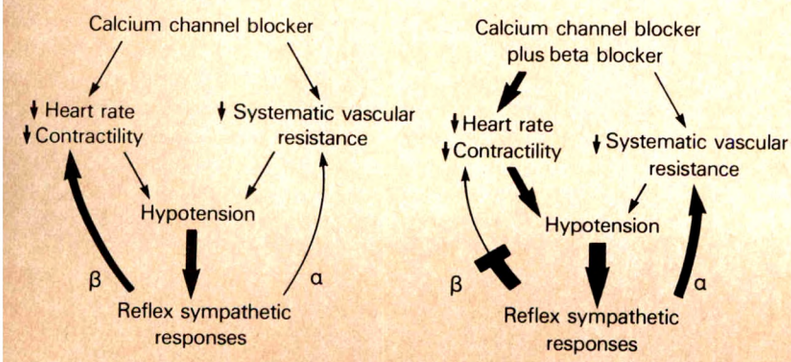

FIGURE 1. Direct and reflex responses induced by calcium-channel blockers alone (**left**) and in combination with β blockers (**right**).

Animal Studies

Early insight into the importance of interactive effects between calcium-channel blockers and β blockers was derived from a variety of canine investigations.[19–21] The short-term administration of intravenous verapamil to dogs resulted in a marked decrease in peripheral resistance, causing reflex sympathetic responses that tended to increase heart rate and cardiac output; direct negative inotropic effects were only partially counteracted by such reflex responses and a decrease in the first derivative of LV pressure (dP/dt) was noted. After pretreatment with propranolol, intravenous verapamil induced similar changes in peripheral resistance but increase in heart rate and cardiac output was partially or totally blunted. Moreover, further increases in LV filling pressures and decreases in dP/dt strongly suggested an additive cardiodepressant effect during combination therapy. Similarly, higher degrees of AV nodal heart block and more frequent episodes of asystole were noted in dogs given intravenous verapamil after pretreatment with propranolol.[22]

In denervated in vitro preparations, nifedipine and verapamil were found to possess comparable intrinsic effects on depressing SA nodal automaticity, AV nodal conduction and myocardial contractility.[23] However, in chronically instrumented conscious dogs,[24] these direct pharmacologic actions were not observed during nifedipine administration, presumably owing to the drugs' potent and preferential vasodilator actions[18] with resulting counterbalancing reflex sympathetic responses. There is a paucity of animal data addressing the concerns of interactive electrophysiologic and hemodynamic effects when either nifedipine or diltiazem are combined with β blockers. In one study,[25] the depressant effects on heart rate, atrial-His (AH) conduction times and AV nodal refractoriness caused by acebutolol were all improved with the concomitant administration of nifedipine, suggesting that secondary reflex responses initiated by nifedipine may protect against deleterious combination drug reactions.

Acute Hemodynamic and Electrophysiologic Studies

In the cardiac catheterization laboratory, Kieval et al[26] studied 20 patients with coronary artery disease and normal LV function (LV ejection fraction ranged from 43 to 79%) receiving relatively small doses of chronic oral propranolol (mean propranolol dose 160 mg/day, mean plasma propranolol level ranged from 66 to 82 ng/ml). Hemodynamic and angiographic variables were measured before and after treatment with intravenous verapamil (0.025, 0.05 or 0.10 mg/kg bolus over 2 min followed by 0.005 mg/kg infusion for 60 min) and the mean plasma verapamil concentration for the entire group at the time of hemodynamic measurements was 168 ng/ml. Intravenous verapamil produced a significant decrease in mean arterial pressure and systemic vascular resistance. Despite the hypotensive effect of verapamil, there was no change in heart rate and no associated improvement in cardiac performance variables (including cardiac index, LV dP/dt and LV ejection fraction). There was no clinical evidence of congestive heart failure as left and right ventricular filling pressures were unchanged. The lack of improvement in cardiac performance in the setting of afterload reduction implies, however, that verapamil caused a mild direct negative inotropic effect. Other investigators have also demonstrated that cardiac output, stroke volume and ejection fraction are unchanged when intravenous verapamil is given *alone* despite similar reductions in systemic vascular resistance.[27,28] Thus, it appears likely that the small implied negative inotropic effects observed by Kieval et al[26] during the short-term administration of intravenous verapamil in patients with preserved LV function receiving small doses of β blockers are not the result of combination drug therapy, but rather are due to verapamil alone.

At the other end of the spectrum, Packer et al[29] evaluated the hemodynamic changes measured during right heart catheterization resulting from the addition of oral verapamil to a group of 15 patients with severe angina at rest and reasonably preserved LV function who were receiving large-dose oral β-blocker therapy (13 patients receiving a mean propranolol dose of 502 mg/day, mean plasma propranolol level 474 ng/ml; 2 patients taking metoprolol 400 mg/day). After the first 120-mg oral dose of verapamil, at which time the average plasma verapamil level was 205 ± 40 ng/ml, there were significant decreases in cardiac index and heart rate associated with increases in both pulmonary capillary wedge pressure and mean right atrial pressure. To determine whether these changes in cardiac performance were due to verapamil alone or to the combination of verapamil and β blocker, β-blocker therapy was withdrawn and the same patient cohort was rechallenged with oral verapamil. Within 24 to 38 hours of β-blocker withdrawal, verapamil produced no significant decreases in cardiac index or heart rate and little change in pulmonary capillary wedge pressure or mean right atrial pressure. These results clearly indicate that the combination of oral verapamil and large-dose β-blocker therapy results in measurable deleterious changes in cardiac function even in patients without severe LV dysfunction (LV ejection fraction ranged from 35 to 78%). Nevertheless, additive drug-related adverse effects were minor; electrophysiologic abnormalities included transient junctional bradycardia in a single patient and hemodynamic disturbances included marked decreases in blood pressure that were unassociated with any symptoms in 2 other patients. Importantly, no instances of clinically overt congestive heart failure were observed.

As with animal investigations, there have been few studies with nifedipine and none with diltiazem examining the short-term additive hemodynamic or electrophysiologic effects in patients receiving long-term β-blocker therapy. Joshi et al[30] studied the effects of adding 10 mg of sublingual nifedipine at the time of cardiac catheterization in 12 patients (8 with coronary artery disease and 4 with no cardiac abnormalities) who were treated with atenolol, 100 mg every 6 hours for 48

hours. Hemodynamic measurements were made during right atrial pacing to a heart rate of 100 beats/min. The addition of nifedipine resulted in marked decreases in mean arterial pressure and systemic vascular resistance. As with verapamil, the expected improvement in cardiac performance usually associated with afterload reduction was not present; although cardiac index did increase, there were no changes in LV ejection fraction or LV end-diastolic pressure, and there was a significant decrease in peak LV dP/dt. Thus, in this small series of patients with normal myocardial function (average LV ejection fraction 61 ± 2%) the combination of small-dose nifedipine and large-dose β blocker caused minor cardiodepressant changes that were similar in direction but lesser in magnitude than those observed with verapamil.

Using a study design combining right heart catheterization and electrocardiographic (ECG)-gated radionuclide angiograms at rest and during exercise, Pfisterer et al[31] studied the short-term hemodynamic effects of combination calcium-channel blocker and β-blocker therapy in 21 patients with angiographically proven coronary artery disease and normal LV function (mean LV ejection fraction 61%). In patients given nifedipine after acebutolol, decreases in ejection fraction, cardiac index and heart rate observed during acebutolol therapy alone were partially normalized with the addition of nifedipine, probably as a consequence of the marked decrease in systemic vascular resistance and the resulting reflex increase in sympathetic stimulation.

The *comparative* effects of verapamil and nifedipine were examined by Winniford et al[32] in 26 consecutive patients with chronic stable angina receiving oral propranolol therapy (mean propranolol dose 234 mg/day) in a short-term study combining hemodynamic evaluation, radionuclide angiography and electrophysiologic testing. In the cardiac catheterization laboratory, measurements were obtained before and after treatment with either intravenous saline solution (n = 6), 0.15 mg/kg of intravenous verapamil (n = 10) or 10 mg of sublingual nifedipine (n = 10). As in previous investigations, intravenous verapamil resulted in decreased heart rate, mean arterial pressure and systemic vascular resistance; cardiac performance variables, instead of improving with afterload reduction, either did not change or showed signs of depressed myocardial contractility. In contrast, nifedipine caused an increase in heart rate, similar decreases in systemic vascular resistance and increases in both cardiac index and ejection fraction. Predictably, verapamil caused prolongation in AH conduction times in all patients without affecting distal conduction, whereas nifedipine had no measurable influence on either AH or HV conduction intervals. Neither verapamil nor nifedipine induced significant changes in resting coronary blood flow as determined using thermodilution coronary sinus catheters.

These hemodynamic and electrophysiologic studies (Table II) show that the short-term administration of either verapamil or nifedipine to patients receiving long-term oral β-blocker therapy further decreases blood pressure and peripheral resistance. Verapamil causes further decreases in heart rate and AV nodal conduction, and appears to depress cardiac function as measured by decreases in cardiac index and LV dP/dt, especially when patients are receiving large doses of β blocker. None of these patients, however, had clinical evidence of LV failure. When nifedipine is added on a short-term basis to small or usual doses of β blockers, there is often an increase in heart rate and either no change or a slight improvement in most indexes of cardiac function. However, when added to large-dose β-blocker therapy, nifedipine may also cause mild depression of myocardial contractility.

There are, however, several critically important limitations to these studies. The likelihood of interactive drug-related adverse effects is certainly dose related (for both β blockers and calcium-channel blockers), is undoubtedly influenced by route and duration of drug administration and is critically dependent on presence or absence of antecedent LV dysfunction and conduction system disease. In the studies summarized in Table II, each patient received a single dose of either β blocker, calcium-channel blocker or both. Whereas patients were usually taking the β blocker on a long-term basis, the

calcium antagonist was administered over the short term. Moreover, and most importantly, all patients had well-preserved LV function. Finally, whereas mean hemodynamic effects of a drug can be assessed in small numbers of patients, such studies cannot take into account the possibility that occasional patients may have aberrant responses. Thus, it is impossible to extrapolate the results of these studies to a more heterogeneous patient population receiving multidrug long-term oral therapy.

It bears emphasizing that additive depression in cardiac performance variables measured during combination verapamil and β-blocker therapy has only rarely been causally associated with episodes of clinical congestive heart failure in patients with preserved LV function.[33] However, in patients with evidence of congestive heart failure, intravenous verapamil *alone* has been shown to induce adverse hemodynamic effects.[34] Moreover, many case reports[35–39] suggest that combinations of either intravenous or oral verapamil and β blockers may cause further clinical deterioration in patients with preexisting hypotension or significant myocardial dysfunction. Similarly, although nifedipine has only rarely been implicated as the sole causative agent leading to hemodynamic or electrophysiologic disturbances in patients with normal LV function,[40] there are preliminary data indicating that nifedipine *alone* may also have clinically important direct negative inotropic effects in patients with congestive heart failure.[41,42] There are also a growing number of reported cases demonstrating that combination therapy with nifedipine and β blockers may result either in severe hypotension or in clinical episodes of congestive heart failure.[43–46] Presumably, attenuation of baroreceptor-mediated compensatory reflexes that normally stimulate cardiac β receptors can unmask intrinsic negative inotropic properties of the drug and precipitate clinical events that are only rarely seen when nifedipine is given alone. Diltiazem, the newest and least extensively studied of the calcium-channel blockers, has only recently achieved widespread clinical use in the United States. Nonetheless, there have already been cases reported of atrioventricular dissociation or sinus nodal arrest or both associated with diltiazem therapy, given alone or in combination with β blockers.[47] Thus, until more clinical experience accrues in patients with depressed LV function and conduction system disease, it is wise to caution against the use of combination therapy with β blockers and *any* calcium-channel blockers in patients who are prone to developing congestive heart failure.

Controlled Clinical Trials

Verapamil: Several clinical trials examined the effects of verapamil plus propranolol in patients with coronary artery disease. We studied 11 patients with severe chronic stable angina and relatively preserved LV function (resting ejection fraction ≥30%) to evaluate the therapeutic efficacy and mechanisms of action of verapamil when administered alone and in combination with β blockers.[4] All patients remained symptomatic after treatment with oral propranolol (mean propranolol dose 225 mg/day, range 160 to 320) and were hospitalized for inpatient evaluation. Patients were given either propranolol (individualized optimal dose established preadmission), placebo or verapamil (320 mg/day followed by 480 mg/day) in single-blind, randomized, triple-crossover fashion. Each drug treatment period was for 48 hours followed by down-titration for 24 hours and 24 hours without medications before advancing to the next drug. After single-drug therapy was completed, all patients were treated with combinations of propranolol and increasing dosages of verapamil (titrated to adverse effect tolerance). Assessment of plasma drug concentrations during active drug administration indicated that steady-state plasma drug levels were achieved for both propranolol (mean plasma level 203 ± 33 ng/ml) and verapamil (mean plasma level with 480 mg/day therapy, 209 ± 29 ng/ml) at the time of exercise testing.

Compared with placebo, which resulted in a mean exercise time of 5.1 min, verapamil (480 mg/day) improved mean exercise duration to 8.5 min ($p < 0.001$) and was more effective than propranolol, which increased mean exercise duration to 6.4 min ($p < 0.005$) (Fig. 2). The combination of verapamil (mean dose 407 mg/day, range 320 to 480) and propranolol (mean dose 255 mg/day) further increased mean exercise performance to 9.8 min, which was significantly better than the results achieved with either propranolol ($p < 0.001$) or large-dose verapamil ($p < 0.01$) (Fig. 2). During exercise, whereas only 2 patients were pain-free with propranolol and 1 was pain-free with verapamil, 9 of 11

patients (82%) had no angina during exercise with the combination of verapamil plus propranolol.

Although 2 patients had transient AV nodal Wenckebach with verapamil alone (1 excluded from study protocol), during combination therapy, no patient had electrocardiographic evidence of new or worsening conduction system abnormalities, as indicated by further PR-interval prolongation, AV nodal heart block or other clinically significant bradyarrhythmias. Moreover, resting LV ejection fraction determined using radionuclide angiography decreased from 48 ± 3% (range 32 to 69) during placebo to 46 ± 3% with propranolol (difference is not significant) and to 44 ± 4% with verapamil ($p < 0.02$ compared with placebo). The addition of verapamil to propranolol did not result in significant additive cardiodepressant effects (ejection fraction 43 ± 4%). LV ejection fraction at rest decreased ≥5% (compared with placebo) in 5 of 11 patients receiving verapamil and in 7 of 11 patients receiving combination verapamil and propranolol therapy. Three patients did describe adverse symptomatic reactions during combination therapy. Two patients noticed postural dizziness associated with orthostatic hypotension (limiting the dose of verapamil) and 2 patients (1 of whom also had dizziness) described exertional dyspnea, 1 with the lowest pretreatment ejection fraction (32%) and another with the greatest decrease in ejection fraction during verapamil alone (from 46 to 31%). Thus, although there were no episodes of overt clinical congestive heart failure noted during combination therapy, in retrospect it seems clear that complaints of exertional dyspnea were early manifestations of LV decompensation.

Bala Subramanian et al[48] studied the comparative efficacy of verapamil (360 mg/day) versus propranolol (240 mg/day) using treadmill exercise testing in 22 patients with chronic stable angina and no evidence of congestive heart failure in a placebo-controlled, double-blind, crossover study consisting of 4-week drug treatment periods. Fourteen patients who remained symptomatic after single-drug therapy were advanced to single-blind combination drug therapy with verapamil (360 mg/day) and propranolol (120 mg/day) for an additional 4 weeks. The mean exercise time for the patient group while taking placebo was 4.8 min; it increased to 6.8 min with propranolol ($p < 0.001$). During combination drug therapy, 7 patients (50%) were without angina during exercise and mean exercise capacity improved to 10.1 min, which was significantly better than either propranolol ($p < 0.01$) or verapamil ($p < 0.05$) alone. In addition, both ST-segment depression and workload achieved during exercise were improved more by combination verapamil-propranolol therapy than by either therapy alone. No serious adverse cardiac or extracardiac effects were encountered during any phase of the drug trial.

Comparing the clinical efficacy of propranolol alone and a verapamil-propranolol combination, Winniford et al[49] investigated 13 men without a history of congestive heart failure who had angina while receiving propranolol therapy (mean propranolol dose 295 mg/day, range 160 to 480). Treatment with propranolol was continued during the entire study and, after open-label verapamil up-titration to establish drug tolerance, all patients were subsequently given either placebo or verapamil (mean verapamil dose 431 mg/day, range 320 to 480) in a randomized, double-blind, crossover study with 2-week drug treatment periods. During propranolol-verapamil therapy, both angina frequency and glyceryl trinitrate consumption diminished significantly compared with propranolol-placebo. The average exercise duration was 6.8 min with propranolol-placebo compared with 8.2 min with propranolol-verapamil ($p < 0.05$). Adverse effects during combination propranolol-verapamil therapy were common; 2 patients had fatigue and dyspnea and 2 others had severe symptomatic sinus bradycardia and junctional escape rhythm. LV ejection fraction (at rest and during exercise) was unchanged after the addition of verapamil to propranolol and no patient had episodes of second- or third-degree AV nodal heart block or objective evidence of LV failure.

These 3 clinical trials convincingly demonstrate that combination therapy with verapamil and propranolol results in additive antianginal efficacy compared with either drug alone as reflected by a decrease in clinical episodes of angina, prolonged exercise capacity and decreased ischemic electrocardiographic changes during exercise. However, the impressive salutary effects were not without some risks. From these 3 trials, it appears that the most serious adverse effects, including hypotension, exertional dyspnea and symptomatic bradycardias, were seen only in the 2 studies using relatively large doses of verapamil and propranolol.[4,49] However, a recent study indicates otherwise.[50] In a double-blind crossover study comparing radionuclide angiographic parameters during verapamil (360 mg/day), propranolol (160 mg/day) and the combination (verapamil 360 mg/day plus propranolol 160 mg/day), 1 of the 19 patients enrolled had symptomatic bradycardia and 3 others had evidence of heart failure during combination therapy.[50] Thus, interactive adverse effects associated with verapamil-propranolol combinations are occasionally unpredictable. The overall frequency of either hemodynamic or electrophysiologic disturbances in the combined studies just reviewed was 14%.[4,48–50]

Nifedipine

Although nifedipine is more often combined with β blockers in outpatient practice than verapamil, it has been the subject of fewer carefully performed clinical trials. Ekelund et al[51] used a double-blind, placebo-controlled, crossover study to compare exercise hemodynamic responses at the end of 3-week treatment periods using a β blocker (metoprolol, 150 mg/day or alprenolol, 300 to 800 mg/day), nifedipine (30 mg/day) and a combination of β blocker and nifedipine in 21 patients with stable exertional angina and no congestive heart failure.[51] The combination of nifedipine and β blocker resulted in a greater diminution in anginal attack frequency and glyceryl trinitrate consumption than could be achieved with either drug alone; furthermore, these favorable effects were associated with an average 41% improvement in total work during exercise com-

pared with placebo. The vast majority of patients (86%) preferred to continue taking combination nifedipine–β-blocker therapy at the completion of the trial and no serious adverse cardiac effects could be attributed to combination drug therapy. Another double-blind, placebo-controlled study using only clinical variables (angina attack frequency and trinitrate consumption) as therapeutic endpoints demonstrated that nifedipine (30 mg/day) plus propranolol (120 mg/day) was clearly superior to placebo or nifedipine alone (30 mg/day) but only marginally better than propranolol alone (240 mg/day). Again, no significant adverse effects were noted in these 20 patients with chronic stable angina during combination nifedipine–β-blocker therapy.[52]

Dargie et al[53] also explored the additive antianginal effect of nifedipine plus propranolol in 16 patients with effort-induced chronic angina and no history of congestive heart failure.[53] Both small and large doses of nifedipine (30 and 60 mg/day) and propranolol (240 and 480 mg/day) were given alone and in combination for 2-week drug treatment periods in a double-blind, placebo-controlled crossover format. Objective study endpoints included patient diaries (recording episodes of chest pain and nitroglycerin consumption), continuous ambulatory ECG monitoring (assessing episodes of ST-segment depression) and precordial ECG mapping during bicycle ergometer exercise (determining extent and severity of exercise-related ischemia). Although both nifedipine and propranolol alone decreased frequency of angina and nitroglycerin consumption, propranolol appeared to be the more effective single agent. Combination therapy with nifedipine and propranolol resulted in decreases in angina frequency and nitroglycerin intake that were only slightly greater than those brought about by propranolol alone. The number of episodes of ST-segment depression during ambulatory ECG monitoring and the area of ST-segment depression during exercise were significantly diminished during combination therapy compared with single drug therapy using either agent. It was observed that nifedipine, 30 mg/day, was less effective than nifedipine, 60 mg/day, for all variables assessed, whereas there was little difference between propranolol, 240 mg/day, and propranolol, 480 mg/day. Adverse effects were frequently described with nifedipine alone (for instance, 40% of patients reported dizziness on standing, 50% of patients had ankle edema), but no significant new or worsening drug-related adverse effects appeared during combination nifedipine-propranolol therapy.

Regrettably, the data generated thus far involving combination nifedipine–β-blocker therapy in controlled clinical trials leave many questions unanswered. The additive antianginal effects in some studies[52,53] were not significantly different from β blockers alone, and the dose of nifedipine used (generally 30 mg/day) may be in the subtherapeutic range for many patients. Nevertheless, there is sufficient combined evidence derived from these investigations,[51,52] from other short-term oral dosing studies,[54] and from studies of patients with unstable ischemic chest pain syndromes[55] indicating that nifedipine–β-blocker treatment in refractory subjects will result in additive therapeutic benefit. Importantly, unlike verapamil, the combination of nifedipine and β blocker was not associated with significant adverse effects in patients without LV dysfunction.

Diltiazem

At present, published reports exploring the potential benefits of combination diltiazem–β-blocker therapy in patients with chronic stable angina remain scanty. Hung et al[56] enrolled 12 patients in a double-blind, crossover, randomized study. The patients performed symptom-limited, upright bicycle exercise while undergoing radionuclide angiography after 2 weeks treatment with diltiazem (360 mg/day), propranolol (240 mg/day) and a combination of diltiazem (360 mg/day) and propranolol (240 mg/day) and placebo. Compared with placebo, diltiazem, propranolol and the combination of diltiazem and propranolol all improved total exercise duration, time to onset of angina and time to ischemic electrocardiographic changes during exercise; there were no differences in any of the active drug treatment groups. The lack of additive antianginal efficacy with combination therapy may be partially explained by the fact that 6 patients with diltiazem alone and 4 patients with propranolol alone were already without angina during exercise testing. In contrast, a preliminary report[57] using more appropriate patient inclusion criteria examined the exercise responses in 12 patients with chronic stable angina treated with diltiazem (180 mg/day), propranolol (240 mg/day) and the combination in a double-blind, placebo-controlled study. It demonstrated significantly greater antianginal benefit during combination therapy compared with either agent alone.

Although diltiazem as a single agent in dosages <240 mg/day is accompanied by only occasional adverse effects,[58–60] Hung et al[56] described a disturbing frequency of interactive adverse drug effects with diltiazem-propranolol combinations; 3 patients had a resting sinus bradycardia <45 beats/min (1 of whom also had orthostatic dizziness), another patient had severe orthostatic dizziness accompanied by postural hypotension and a fifth patient had short episodes of sinoatrial pauses. Other investigators using similar dosages of diltiazem-propranolol combinations in patients with coronary vasospasm have also described a tendency toward severe sinus bradycardia.[61] Finally, there was no evidence of LV dysfunction or episodes of clinical congestive heart failure during any treatment group in this study,[56] but the number of patients treated was too small to derive any conclusion concerning the possibility of LV dysfunction developing with diltiazem–β-blocker therapy.

Comparative Clinical Efficacy

Attempts to compare relative therapeutic efficacy of different calcium-channel blockers used in combination with β blockers are frought with complex methodologic considerations. Factors that can never be equalized retrospectively include drug dosage (for both calcium-channel blocker and β blocker), duration of therapy, vagaries of study design, such as differences among exercise protocols, and patient selection criteria. Nev-

ertheless, given these considerable limitations and the small number of controlled clinical trials available for analysis, the combination of verapamil and propranolol would appear to be the most beneficial, if the percentage of change in exercise performance is used as the sole criterion for additive therapeutic efficacy (Fig. 3).

An alternative approach to assess relative therapeutic potency among various calcium-channel blockers when combined with β blockers was used by Bassan et al.[62] Ten men with stable angina not fully relieved by optimal doses of propranolol (mean propranolol dose 218 mg/day, range 60 to 360) were given on each of 4 separate days, in addition to chronic propranolol, a single dose of either nifedipine (10 mg), verapamil (120 mg), isosorbide dinitrate (5 to 30 mg) or placebo in double-blind crossover fashion. Symptom-limited bicycle exercise tests were performed hourly for 8 hours and all 3 agents were shown to prolong exercise duration by at least 50% by the first hour ($p < 0.001$) with a gradual diminution in antianginal effect by the eighth hour ($p < 0.01$). Although no group differences in relative therapeutic efficacy could be demonstrated among the agents, in half the patients either the magnitude or duration of beneficial effects favored one or another vasodilator. Caution, however, is advised in the interpretation of such short-term oral dosing studies involving vasodilators. Marked preload and afterload reduction associated with short-term, single-dose treatment is often attenuated during continuous therapy, resulting in diminished antianginal effects. Therefore, attempts to extend these findings to the more realistic clinical setting of long-term oral multidrug therapy may not be justified.

Mechanisms of Action

There are many underlying pathophysiologic mechanisms responsible for the favorable clinical responses seen in patients with coronary artery disease treated with calcium-channel blockers. Like other antianginal agents such as nitrates and β blockers, each of the calcium-channel blockers (to varying degrees) has the effect of reducing several of the hemodynamic determinants of myocardial oxygen demand. Pressure-rate product, which loosely reflects myocardial oxygen consumption, is reduced compared with placebo, at rest and during matching levels of exercise with single drug therapy using verapamil[4–6,63] (Fig. 4), nifedipine[7,8,64] and diltiazem.[10,65] Moreover, at symptom-limited termination of exercise, the pressure-rate product attained is similar to placebo endpoint values (Fig. 4). These findings have been interpreted to imply that the predominant mechanism of action of calcium-channel blockers is restricted to influences on oxygen demand and unrelated to changes in coronary vasomotor tone and myocardial oxygen delivery. Yet, this appears to be an oversimplification of a complex series of interrelated physiologic events. Quantitative coronary angiographic techniques have demonstrated that verapamil is a mild epicardial coronary vasodilator in patients with coronary disease, and also inhibits neurally mediated and ergonovine-induced vasoconstriction.[12] Recently, nifedipine has been shown to increase great cardiac vein blood flow (and peak pressure-rate product at angina) while reducing anterior regional coronary resistance in those patients with stable effort angina manifesting the greatest antianginal effects.[66] Closer examination of individual patient data from reported studies[4] also re-

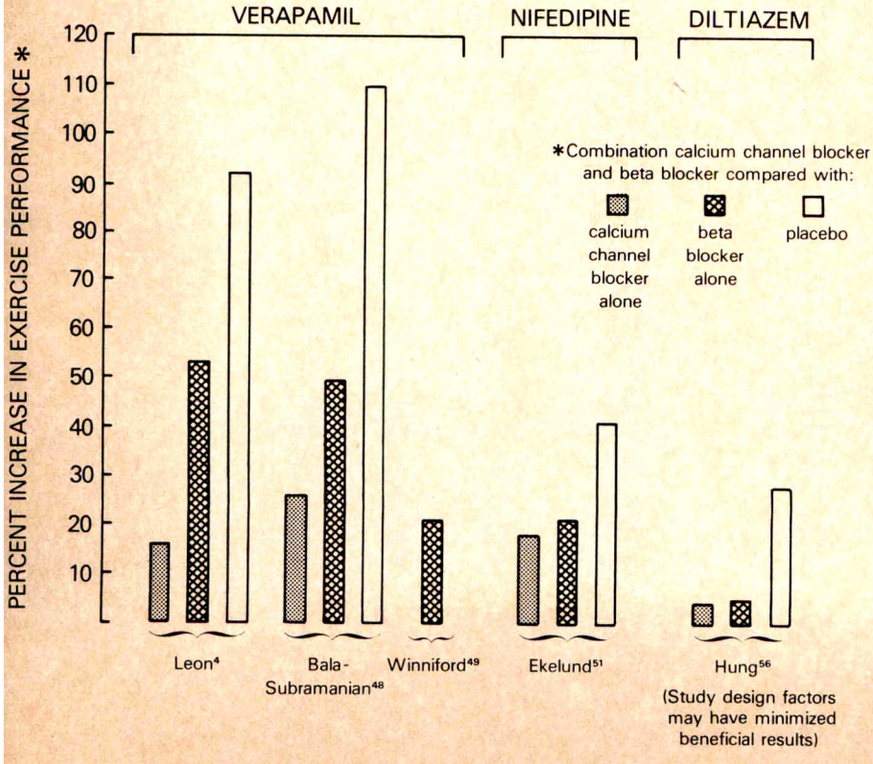

FIGURE 3. Percent increase in exercise performance during combination calcium-channel blocker (verapamil, nifedipine or diltiazem) and β-blocker therapy compared with placebo, calcium-channel blocker alone and β blocker alone.

veals that some patients have marked increases in peak pressure-rate product achieved during exercise after treatment with verapamil, suggesting a primary increase in myocardial oxygen supply. Finally, if changes in diastolic filling characteristics caused by calcium-channel blockers have therapeutic consequences in patients with coronary artery disease, a contributing mechanism would include an improvement in transmyocardial coronary perfusion.

The assumption that pressure-rate product analysis incorporates all factors influencing myocardial oxygen demand is also an oversimplification. Calcium-channel blockers, by virtue of their negative inotropic effects or change in loading conditions that alter LV geometry, can modify myocardial oxygen demand independent of their effects on heart rate and blood pressure. In addition, animal and human studies suggest that verapamil may cause changes in *regional* systolic function, which are most marked in ischemic myocardium; these effects are different from those observed with β-blocking agents.[50,67] The situation is further complicated by the fact that underlying pathophysiologic mechanisms responsible for angina may differ among patients, and include, to varying degrees, fixed atherosclerosis, superimposed coronary vasospasm and reduced ventricular compliance. It would therefore be difficult to define a specific mode of action of a calcium-channel blocker in an individual patient, as the drugs could exert their salutary effects by decreasing myocardial oxygen demand, increasing myocardial oxygen supply or improving LV compliance.

Although the mechanism of action of a calcium-channel blocker as a single agent in the treatment of chronic stable angina is controversial, there is a clearer explanation for the additional benefits derived from combination therapy with β blockers. Compared with either class of drug alone, the addition of β blockers to calcium-channel blockers results in further decrease in heart rate, blood pressure and, consequently, pressure-rate product both at rest and during exercise, causing a significant additive diminution in myocardial oxygen demand (Table III). Moreover, concomitant calcium-channel blocker and β-blocker therapy initiate offsetting physiologic responses that attenuate the

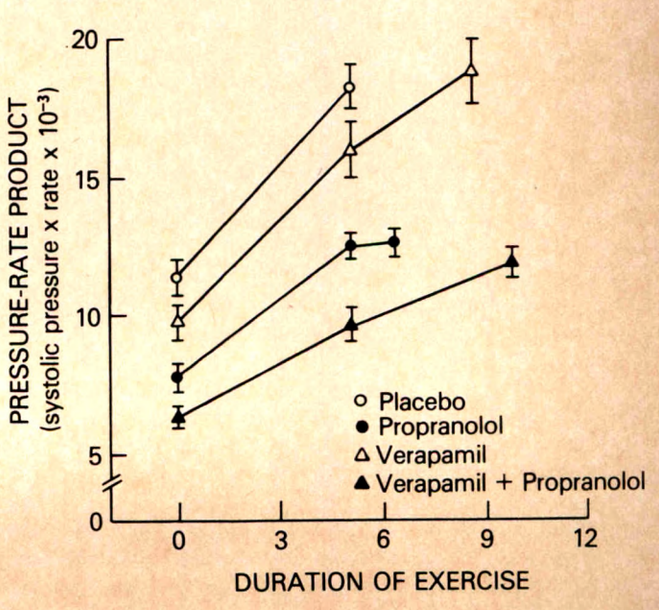

FIGURE 4. Pressure-rate product responses at rest before exercise, at placebo endpoint of exercise and at termination of exercise. Data are expressed as mean ± standard error of the mean with various drug therapies.

potentially negative effects of each individual drug (Table IV). For instance, baroreceptor-mediated reflexes causing sympathetic stimulation of the heart induced by calcium-channel blocker therapy may diminish their effectiveness by blunting their direct negative chronotropic and inotropic influences on myocardial oxygen demand; combination therapy with β blockers would partially negate these reflex responses and improve therapeutic efficacy. Similarly, unopposed α-adrenergic–mediated coronary vasoconstriction in β-blocked patients would be partially or completely reversed during combination therapy with calcium-channel blockers. Thus, combined drug therapy appears beneficial in relieving symptoms of angina, not only because of individual favorable drug actions but also because, when used together, each drug may serve to oppose the unfavorable cardiovascular effects of the other.

Therapeutic Implications

The proper clinical use of combination calcium-channel blocker and β-blocker therapy in patients with chronic stable angina still remains controversial. At the present time, it would be impossible to propose a universal formula that would apply to all patient subsets in all clinical circumstances. Therefore, decisions regarding combination therapy must be made on a case-by-case basis and are dictated by careful attention to each of the following factors.

Choice of calcium-channel blocker: The calcium-channel blockers possess diverse and differing pharmacologic properties. Heart rate-lowering vasodilators, such as verapamil and diltiazem, appear to be the most effective antianginal agents and have the lowest incidence of significant adverse *extracardiac* effects. However, when combined with β blockers, these drugs also have the highest incidence of adverse *cardiac* effects. Verapamil may precipitate or exacerbate congestive heart failure and may cause bradyarrhythmias more often originating from the AV node, whereas diltiazem more frequently causes bradyarrhythmias originating from the SA node. On the other hand, a vasodilator that lacks heart rate-lowering effects, such as nifedipine, appears to be a less effective antianginal agent, alone or in combination with β blockers. Further, in therapeutically important dosages (from 60 to 120 mg/day), nifedipine has the highest incidence of significant adverse *extracardiac* effects. It is important to note that nifedipine added to β blockers is generally viewed as a safe drug combination from the standpoint of adverse *cardiac* effects; rarely is congestive heart failure or bradyarrhythmias a problem, and additive hypotension can usually be reversed with careful dose titration.

Dose of calcium-channel blocker and β blocker: Although increasing doses of calcium-channel blockers tend to favor augmented therapeutic benefit,[4,6,53] during combination therapy with β blockers attempts to use larger doses must be tempered by the potential for serious additive hemodynamic or electrophysiologic consequences. For example, the only study demonstrating a significant decrease in LV ejection fraction with oral verapamil alone used 480 mg/day dosages;[13] in contrast, other studies using similar radionuclide angiographic techniques and lower dosages of verapamil (320 mg/day) found no changes in ejection fraction.[68] Similarly, unusually large doses of β blockers were implicated by Packer et al[29] as the major cause for additive cardiodepressant effects found in their study of combination drug therapy. Given the data thus far available, it seems prudent when contemplating combination therapy to treat with somewhat smaller than normal doses of both calcium-channel blockers (especially verapamil and diltiazem) and β blockers.

High-risk patient subgroups: Patients with clinically apparent LV dysfunction, a propensity for developing bradyarrhythmias (either at the SA or AV nodal level) or hypotension should be considered at high risk to develop complications from combination calcium-channel blocker and β-blocker therapy. Although most studies have carefully excluded patients with moderate or severely depressed LV function, it seems clear from hemodynamic evidence that combination therapy in such patients should favor nifedipine; diltiazem and especially verapamil should be completely avoided or used at small dosages with extreme caution. Verapamil has been shown to depress sinus nodal function in patients with sick sinus syndrome[69] and diltiazem has the greatest negative chronotropic effects among all calcium-channel blockers.[70] Therefore, neither should be used with β blockers in patients with signs of sick sinus syndrome, including severe sinus bradycardia at rest. Verapamil, and to a lesser extent diltiazem, are also relatively contraindicated during combination therapy in patients with evidence of antecedent AV nodal disease (marked PR-interval prolongation or higher degrees of AV nodal heart block). Finally, in patients with borderline hypotension, treatment with potent vasodilators like nifedipine, either alone or particularly in combination with β blockers, may be extremely hazardous and should be approached with caution.

Other drug interactions: In addition to β-adrenergic–blocking agents, other cardioactive medications combined with calcium-channel blockers may result in deleterious interactive effects. Drugs with negative inotropic properties, such as disopyramide, may potentiate the cardiodepressant actions of calcium-channel blockers (especially with β blockers) and are relatively contraindicated. During combination calcium-channel blocker and β-blocker therapy, maintenance of circulatory homeostasis is disproportionately dependent upon reflex α-adrenergic sympathetic responses (Fig. 1, right). Therefore, other potent arteriolar dilators (such as hydralazine, prazosin and captopril) and drugs with central or peripheral α-adrenergic–blocking properties (such as clonidine, methyldopa and possibly quinidine) may also precipitate severe symptomatic hypotension when added to calcium-channel blockers (particularly nifedipine). Finally, intrinsic negative chronotropic and AV nodal depressant effects of verapamil and diltiazem are exaggerated in the presence of both β blockers and digoxin, independent of the changes induced by calcium-channel blockers on digoxin metabolism and clearance.[71]

TABLE IV Factors Influencing Myocardial Oxygen Supply-Demand Relation During Treatment with Calcium-Channel Blockers, β Blockers and the Combination

	Calcium-Channel Blockers				Calcium-Channel Blockers + β Blockers		
	V	N	D	β Blockers	V	N	D
Myocardial oxygen supply							
Coronary vasomotor tone	↓↓	↓↓	↓↓	↑	↓	↓	↓
Diastolic filling	↑↑	↑	0	0	↑↑	↑	0
Myocardial oxygen demand

LV systolic wall tension	↓	↓↓	↓	↓	↓↓	↓↓↓	↓↓
Contractility	↓↓	0	↓	↓	↓↓↓	↓	↓↓

D = diltiazem; LV = left ventricular; N = nifedipine; V = verapamil.

As our experience broadens, several general statements concerning combination calcium-channel blocker and β-blocker therapy may be helpful in guiding the practitioner. First, combination therapy should be reserved for only those patients with chronic stable angina who continue to have severe symptoms despite an adequate trial using reasonable therapeutic dosages of single agents. At the present time, most physicians initiate antianginal therapy using combinations of long-acting nitrates and β blockers. Instead of simply adding calcium-channel blockers to this regimen in patients with refractory symptoms, we prefer to substitute for the β blocker a heart-rate-lowering calcium-channel blocker (either verapamil or diltiazem) as single-drug therapy. There is ample evidence from controlled clinical trials to suggest that verapamil and diltiazem have at least equivalent therapeutic efficacy compared with β blockers in patients with chronic stable angina.[2,4,6,48,56] Moreover, in a given person, either one or the other class of drugs may be significantly more effective, lending credence to the proposal that each class should be tried individually before combination therapy is contemplated. Perhaps patients who preferentially respond to calcium-channel blockers are more susceptible to dynamic changes in coronary vasomotor tone as a contributing pathophysiologic mechanism of angina, whereas patients who respond to β blockers have fixed occlusive atherosclerotic disease as the dominant mechanism precipitating angina. After substitution calcium-channel blocker therapy is attempted, patients who remain symptomatic are candidates for combination therapy with β blockers. We recommend careful upward titration starting with relatively small doses of β blockers, so that heart rate and blood pressure responses are further blunted but dangerous drug-related adverse effects are minimized. This approach has the advantage of optimizing patient compliance and cost-effectiveness (by favoring single-drug therapy whenever possible), while reducing the possibility of harmful drug reactions.

Another approach that has gained much popularity in clinical practice involves the immediate addition of nifedipine to β blockers (and nitrates) in resistant patients. Although this prescribing pattern is generally safe and is simpler than substitution drug therapy, we find it somewhat less desirable; compliance is poorer, cost is greater and nifedipine–β-blocker combinations are probably less effective than verapamil or diltiazem–β-blocker combinations. Importantly, in patients with significant antecedent LV dysfunction or conduction system disease arising in slow-channel dominated tissues, combination calcium-channel blocker and β-blocker therapy is relatively contraindicated. If necessary, combination therapy in such patients should favor nifedipine rather than verapamil of diltiazem and would mandate close patient monitoring and follow-up.

There is little doubt that the use of calcium-channel blockers combined with β blockers may provide much needed therapeutic benefit in patients with refractory chronic stable angina. However, when used in routine clinical practice, such combinations must be treated with great respect and require that patients be carefully selected and closely observed.

Use of Calcium Antagonists in Ventricular Dysfunction

MARTIN A. JOSEPHSON, MD, and BRAMAH N. SINGH, MD, PhD

Calcium antagonists are now widely used in a variety of cardiocirculatory disorders, many of which are associated with varying levels of depressed myocardial function. Thus, the hemodynamic effects of calcium antagonists in patients with normal as well as depressed ventricular function are clinically relevant. None of the 3 agents verapamil, nifedipine or diltiazem exerts significant negative inotropic effects in patients with relatively normal myocardial function, although increases in left ventricular end-diastolic pressure may occur with verapamil and possibly diltiazem. In a setting in which ischemia, hypertension or arrhythmias contribute to cardiac failure, all 3 agents may ameliorate myocardial decompensation if they reverse the precipitating causes. In patients with depressed myocardial function, the effects of diltiazem are not known; verapamil may depress myocardial function, especially if the ventricular filling pressure is increased. Nifedipine generally has little depressant action in this setting and usually improves cardiac function, especially if the sympathetic reflexes are intact. However, hemodynamic deterioration after nifedipine administration has been reported. Thus, the available data do not support the use of calcium antagonists as afterload-reducing agents in heart failure and suggest caution in the use of these agents in patients with impaired ventricular performance.

(Am J Cardiol 1985;55:81B–88B)

As a pharmacodynamic and therapeutic concept, calcium antagonism has recently become an important framework by which the properties of a large and chemically heterogeneous group of compounds may be delineated.[1] Such compounds are now known to hold much promise in the management of a wide variety of cardiocirculatory disorders,[2–4] especially ischemic myocardial syndromes, hypertension, obstructive cardiomyopathies and certain forms of cardiac arrhythmias. In many of these disorders myocardial function is often compromised to a variable degree; thus agents that have a potentially depressant effect on cardiac muscle might aggravate the existing level of ventricular performance even in therapeutic doses and concentrations. By the very nature of their effect on the myocardial slow channel, calcium antagonists exert a negative inotropic action best demonstrated in isolated cardiac muscle.[5] These agents are also potent peripheral vasodilators; the impedance reduction that they thereby cause may variably offset their negative inotropic proclivity, permitting their relatively safe application in cardiovascular therapeutics. It is becoming increasingly clear, however, that different types of calcium antagonists differ significantly in this regard. Furthermore, the clinical experience that has accrued raises 2 significant issues regarding the safety of these drugs when used in patients with myocardial dysfunction. The first is the safety of these agents when they are used to treat patients with various cardiovascular disorders such as angina or coronary vasospasm in patients with reduced ventricular function. The second is the safety of these agents, by virtue of their afterload-reducing effects, in the treatment of patients with heart failure.

This report examines these issues with respect to verapamil, nifedipine and diltiazem and with particular attention to their net pharmacodynamic properties. Initially, the relevant pharmacologic similarities and differences among these compounds will be reviewed; then their hemodynamic actions in patients with preserved as well as reduced ventricular function will be discussed. The clinical significance of these observations is then explored.

Pharmacologic Considerations

The effects of calcium-channel blocking drugs on myocardial contractility differ significantly in isolated preparations compared with those in intact animals and man. In vitro experiments in which reflex activity is absent demonstrate that all 3 calcium antagonists available for clinical use in the United States exert a dose-dependent inhibition of myocardial contractility that is reversed either by increasing the extracellular concentrations of calcium, or by agents that augment

the transmembrane transfer of calcium ion.[6] The potency of various calcium antagonists in uncoupling excitation-contraction in isolated cardiac tissues correlates well with their negative inotropic propensity and their potency to inhibit the slow calcium channel. In this regard, on the basis of molar concentrations, nifedipine is the most potent, diltiazem the least, and verapamil has an intermediate range of potency.[5,7,8] The same rank order of potency has been found for these compounds with respect to their ability to relax smooth muscle cells in vitro and to dilate arteries and arterioles in intact animals and presumably in man. For example, nifedipine, a prototype of the dihydropyridine subgroup of calcium antagonists, is the most potent for reducing systemic vascular resistance, an effect that is likely to be accompanied by marked reflex increases in heart rate and cardiac pump function.[9] The latter is particularly striking with nifedipine, because this drug has no significant primary depressant effect on sinoatrial (SA) nodal automaticity or myocardial function in intact animals and man. In contrast, verapamil and diltiazem have less marked peripheral vasodilator effects and often exhibit significant direct depressant effects on SA nodal automaticity. This, in turn, tends to attenuate the myocardial contractility and reflex increases in heart rate and myocardial performance that result from the peripheral dilator effects of verapamil and diltiazem. Thus, based on pharmacologic considerations, somewhat greater negative inotropic effects with verapamil and diltiazem might be expected than with the dihydropyridine type of calcium antagonists.

Hemodynamic Effects of Calcium Antagonists in Patients Without Significant Impairment of Ventricular Function

The pharmacologic and clinical considerations just outlined suggest that the net hemodynamic effects of calcium antagonists in patients with heart disease are likely to be the result of a complex interplay of simultaneous alterations in ventricular preload, afterload, myocardial contractility, coronary blood flow and heart rate, variably modulated further by the level of intrinsic ventricular function, the status of the autonomic nervous system, the presence or absence of myocardial ischemia and the properties of the various calcium antagonists themselves.[10,11] The characterization of the hemodynamic profiles of nifedipine, verapamil and diltiazem in patients with relatively well-preserved ventricular function permits a comparison of their effects in patients with reduced ventricular performance.

Nifedipine: When administered either intravenously or sublingually, nifedipine produces the most profound vasodilatation in the periphery; this leads to reflex increases in cardiac pump function in the setting of both normal and impaired ventricular function. For example, a 20-mg sublingual dose of nifedipine was found to increase cardiac index (18%) with corresponding directional changes in heart rate and the first derivative of left ventricular pressure (dP/dt_{max}).[12] Reflex augmentation of myocardial function after this dose administration was also documented by an accompanying increase in the left ventricular (LV) ejection fraction (9%) and the mean velocity of circumferential fiber shortening (35%). These changes occurred without alterations in end-diastolic pressure or end-diastolic volume.[12] We emphasize, however, that while nifedipine clearly does not depress myocardial function in most patients, its safety in this regard is largely due to its potent peripheral vasodilator action, which lead to ventricular unloading and activation of sympathetic reflexes. These effects nullify and even reverse nifedipine's intrinsic negative inotropic actions. However, if the reflex effects were attentuated either by disease or concomitant use of sympatholytic drugs, significant depressant effects of the compound are likely to become apparent.

Verapamil: Numerous investigators have studied the hemodynamic effects of intravenously administered verapamil in patients with cardiac disease,[13–15] and data have also appeared recently (discussed later) on diltiazem.[16] Figure 1 illustrates the typical hemodynamic

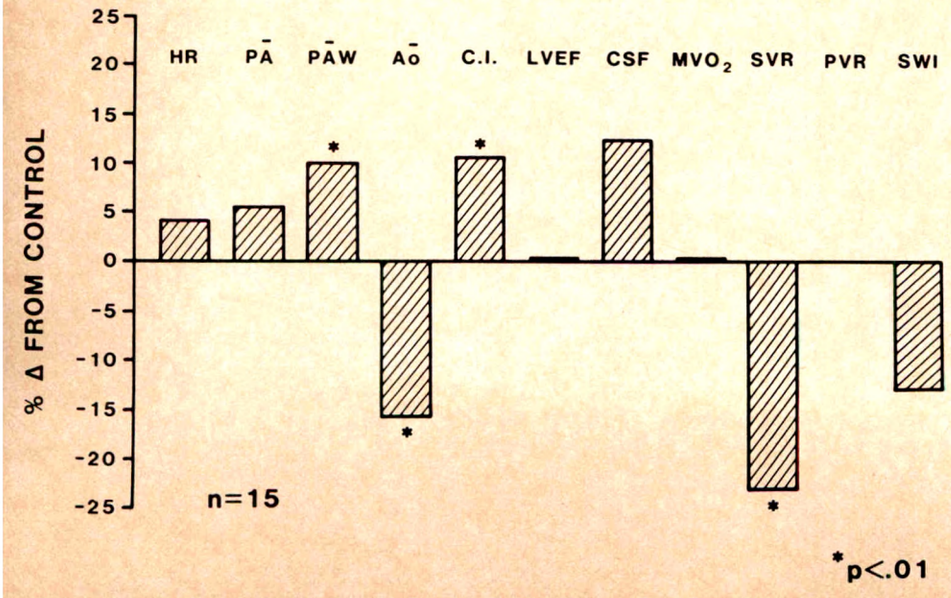

FIGURE 1. Effects of intravenous verapamil on systemic and coronary hemodynamic features and left ventricular ejection fraction in 15 patients with coronary artery disease. $A\bar{o}$ = mean aortic pressure; CI = cardiac index; CSF = coronary sinus flow; HR = heart rate; LVEF = LV ejection fraction; $M\dot{V}O_2$ = myocardial oxygen consumption; $P\bar{A}$ = mean pulmonary artery pressure; $P\bar{A}W$ = mean pulmonary capillary wedge pressure; PVR = pulmonary vascular resistance; SVR = systemic vascular resistance; SWI = stroke work index.

changes produced by the administration of intravenous verapamil (0.145 mg/kg bolus injection followed by 0.005 mg/kg/min continuous infusion) in a series of 15 patients with chronic stable angina undergoing diagnostic cardiac catheterization.[15] This group of patients had relatively preserved ventricular function with a mean ejection fraction of 56%. In this study, the 23% decrease in systemic vascular resistance and 16% decrease in mean arterial pressure document the peripheral vasodilator effect of verapamil. Despite the 11% increase in cardiac index, the associated 10% increase in the pulmonary capillary wedge pressure and a 13% decrease in the stroke work index undoubtedly reflect the intrinsic myocardial depressant effect of verapamil. This is supported by the findings of Singh and Roche,[13] which showed that 10 mg of verapamil given intravenously to patients with cardiac disease led to an approximately 10% decrease in the LV dP/dt_{max}. The hemodynamic findings reported by Chew et al[15] and Singh and Roche[13] are very similar to those described by Ferlinz et al[14] insofar as these investigators found a modest increase in the filling pressures of the ventricles. However, Ferlinz et al found a small but apparently significant increase in LV ejection fraction using contrast left ventriculography; in contrast, Chew et al from our laboratory reported no change, using radionuclide ventriculography. It is conceivable that the difference between the 2 reports may reflect differences in patient populations as well as the differing methods used to determine LV ejection fraction. It is also possible that an increase in LV ejection fraction might occur after the administration of verapamil in some patients if the drug were given at a time active ischemia were present, with an improvement in the degree of myocardial ischemia contributing to the improved ejection fraction. An improvement in LV ejection fraction after administration of verapamil was demonstrated in patients in whom a decrease in this parameter was induced by rapid atrial pacing[17] or by supine bicycle exercise;[18] these maneuvers are known to produce ischemia and impair ventricular function in the setting of coronary artery disease. Such observations emphasize that in the setting of myocardial ischemia antianginal drugs such as verapamil are likely to improve rather than depress ventricular ejection fraction.

Diltiazem: The data from our laboratory on the hemodynamic effects of intravenously administered diltiazem (0.16 to 0.25 mg/kg bolus injection) are summarized in Figure 2. The group of patients studied had coronary artery disease and clinical characteristics similar to those reported in our study with verapamil.[15] The mean LV ejection fraction for the diltiazem group was also similar, averaging 63%. The 22% decrease in systemic vascular resistance, the 12% decrease in mean arterial pressure and the 8% increase in the cardiac index associated with a small but not statistically significant decrease in the stroke work index resemble the changes after verapamil administration. Neither agent produced significant changes in heart rate, but a modest increase in the mean capillary wedge pressure occurred with diltiazem as we[16] found in the case of verapamil. These data suggest a mild degree of impairment of ventricular function. As with the intravenous administration, neither verapamil[18] nor diltiazem[19] given on a long-term oral basis was found to significantly depress LV ejection fraction in patients with coronary artery disease who have relatively well-preserved ventricular ejection fraction.

When the overall data on the hemodynamic effects of verapamil, nifedipine and diltiazem in patients with relatively well-preserved ventricular ejection fraction are considered in light of the aforementioned data, the negative inotropic effects of these agents, clearly evident in isolated cardiac muscle, are almost completely balanced by their afterload-reducing properties. Thus, when given on either a short-term basis by the intravenous route or on a long-term basis by mouth, the use of these agents is unlikely to be accompanied by clinically significant depression of myocardial function. In general, this is consistent with clinical experience. However, as indicated earlier, there are clinical situations in which these agents might be expected to exert a potentially depressant effect on cardiac performance (discussed later).

Effects of Calcium Antagonists in Acute Myocardial Infarction

Only limited data are available on the effects of calcium antagonists in patients with acute myocardial infarction. However, intravenous doses of verapamil

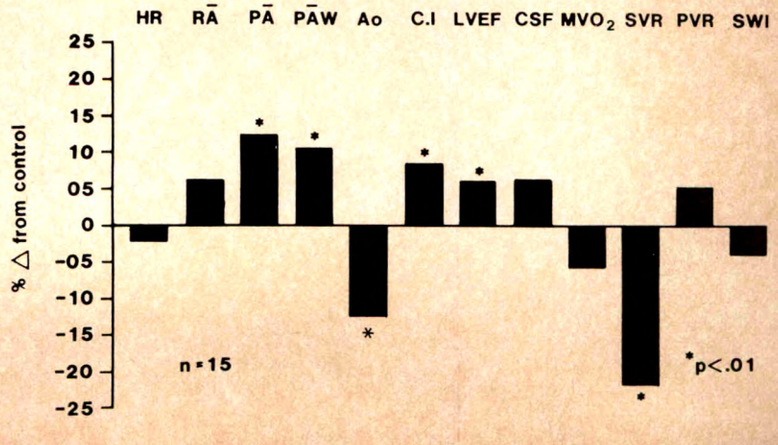

FIGURE 2. Effects of intravenous diltiazem on systemic and coronary hemodynamic features and left ventricular ejection fraction in patients with coronary artery disease. RĀ = right atrial pressure. Other abbreviations as in Figure 1.

(0.145 mg/kg as a bolus injection followed by 0.005 mg/kg/min continuous infusion) in patients with uncomplicated myocardial infarction produced hemodynamic effects identical to those in patients with relatively normal LV ejection fraction undergoing diagnostic catheterization for the evaluation of coronary artery disease.[15] Of particular interest was the observation that in both subsets of patients the drug had no depressant effect on LV ejection fraction determined either by contrast or radionuclide ventriculography. Comparable data for nifedipine or diltiazem given parenterally to patients with acute myocardial infarction are not available at present. However, all 3 drugs were investigated by Theroux et al[20] in patients with uncomplicated acute myocardial infarction given single oral doses of the respective agents. The mean data are summarized in Figure 3, which emphasizes the somewhat differing pharmacologic effects of the 3 compounds. For example, heart rate after nifedipine increased by 6%, decreased by 11% after diltiazem and remained unchanged after verapamil administration. After nifedipine, the mean arterial pressure decreased by 12% compared with a 6% decrease after diltiazem, while the decrease for verapamil was intermediate in magnitude. It is noteworthy that cardiac index did not change significantly in any of the 3 groups, although there was a trend for it to increase after nifedipine. As discussed earlier, the differences in the effects of these compounds on heart rate and systemic vascular resistance reflect their differing interactions with the autonomic nervous system and their varying potencies as peripheral vasodilators. Furthermore, the data relative to heart rate changes suggest that when a calcium antagonist must be given to a patient with ischemia, but with bradycardia also, nifedipine might be preferable to the other 2 compounds. However, the data do not permit conclusions regarding the patterns of hemodynamic changes that may be found with these compounds in patients with various LV dysfunctions and after long-term therapy. The limited data that are available are discussed later.

Calcium Antagonists in the Setting of Ventricular Dysfunction and Hypertensive Crises

When LV dysfunction occurs as a result of myocardial ischemia or other causes (for example, hypertensive crises) that may respond to calcium antagonists, beneficial effects might result from the use of these agents. In other instances the response may be unpredictable, varying from a depressant one to an improvement in ventricular performance, depending on the properties of an individual calcium antagonist and the overall clinical situation.

Nifedipine: In a study involving 15 patients with stable angina and a mildly decreased LV ejection fraction of 49%, which decreased to 42% with exercise, 20 mg of oral nifedipine resulted in improved resting and exercise ejection fractions (52% and 47%, respectively).[21] Additionally, segmental wall motion determined by radionuclide ventriculography and myocardial perfusion evaluated by thallium-201 scintigraphy were improved. During pacing-induced ischemia, nifedipine

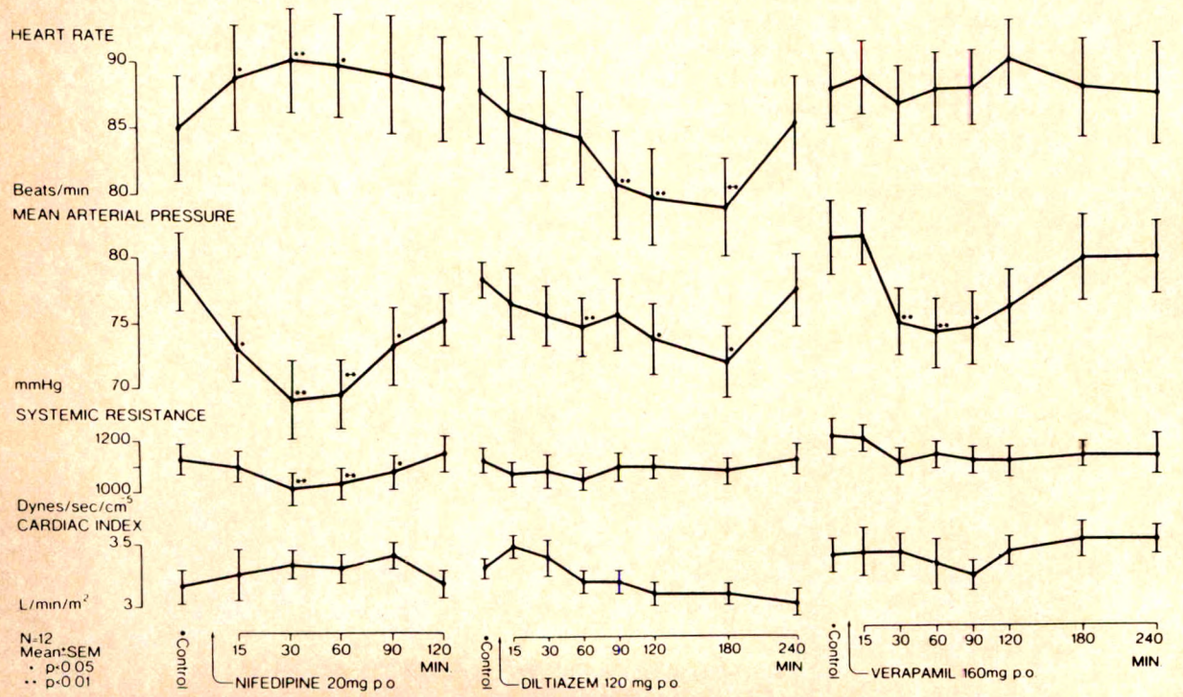

FIGURE 3. Comparative effects of single doses of 3 calcium antagonists in patients with recent acute myocardial infarction. The data shown are mean ± standard deviation (adapted from Theroux et al[18]). Note that nifedipine produces most profound decrease in arterial pressure with reflex increases in heart rate. Effect is least with diltiazem, which *decreases* heart rate; effect of verapamil is intermediate between 2 other compounds. PO = orally; SEM = standard error of the mean.

permitted pacing to higher heart rates before the onset of angina,[22] an effect probably due to the decrease in the myocardial oxygen demands rather than to an increase in myocardial flow. These overall data on the effects of nifedipine on ventricular dysfunction induced by myocardial ischemia emphasize the fact that the beneficial effect of the calcium antagonist on ventricular function is an indirect one mediated through the amelioration of ischemia, an effect that might be expected to occur with all effective antianginal or antiischemic compounds. A similar "indirect" beneficial effect has been demonstrated in hypertensive patients[23–25] given sublingual or oral doses of nifedipine. A similar effect with oral doses of the drug has been reported to persist during 3 weeks of long-term therapy.[24] It is noteworthy that in 10 patients with hypertensive crisis (blood pressure >220/120 mm Hg), all achieved an acceptable hypotensive response after nifedipine administration.[25] In patients in heart failure in this same study, pulmonary edema was promptly relieved by nifedipine. Similarly, Guazzi et al[24] reported that 3 patients with acute left-sided heart failure caused by hypertension had significant improvement after 10 mg doses of nifedipine were given at intervals of 1 hour. Significant decreases in systemic and pulmonary arterial pressures associated with increases in cardiac output accompanied the clinical improvement effected by nifedipine. Further documentation of the beneficial effect of nifedipine in this setting was provided by Polese et al[26] in 7 patients with congestive heart failure complicating severe hypertension. Nifedipine was given 10 mg sublingually. A significant decrease in both systolic and diastolic internal ventricular dimensions measured echocardiographically followed the administration of nifedipine; there was also improvement in the mean velocity of circumferential fiber shortening and in the left and right ventricular ejection phase indexes. Similar findings in patients with various degrees of LV dysfunction were demonstrated by Ludbrook et al[12] after 20-mg sublingual doses of nifedipine. In this study, a significant decrease in LV preload and end-diastolic pressure was seen only in those patients with increased LV end-diastolic volumes ≥90 ml/m^2. It was in this group of patients with more marked ventricular dysfunction that the most striking decrease in systemic and pulmonary vascular resistance and significant increase in cardiac index occurred.

We emphasize that the use of nifedipine in the setting of cardiac failure, whether overt or latent, may not always be free of adverse effects. For example, Brooks et al[27] reported clinical deterioration, that is, development of severe hypotension, in 2 patients with severe congestive cardiac failure after nifedipine. In these patients, although the pulmonary capillary wedge pressure was decreased by nifedipine, cardiac index decreased markedly and calcium plus epinephrine administration was necessary to restore adequate cardiocirculatory function. It must be assumed that in certain subsets of patients with cardiac failure, the reflex mechanisms activated by peripheral dilatation after nifedipine are inadequate to offset the intrinsic negative inotropic effects of the calcium antagonist.

Verapamil: Although verapamil has been evaluated more extensively than diltiazem in patients with myocardial dysfunction, adequately controlled data in a similar clinical subset of patients are also limited. In sharp contrast to verapamil's lack of adverse hemodynamic effects in patients with normal or near normal ventricular performance, Chew et al[15] found clinical and hemodynamic deterioration in a small number of patients with severely decreased LV ejection fraction (<35%) and increased pulmonary capillary wedge pressure (>18 mm Hg) after intravenous verapamil (0.145 mg/kg given as a bolus injection followed by continuous infusion at 0.005 mg/kg/min). Chew's findings, however, conflict with those from Ferlinz et al.[28] The differences between the hemodynamic effects of verapamil in patients with depressed ventricular function and increased wedge pressures and those without these resting abnormalities are illustrated in Figure 4.

On the basis of these results, it would appear unjustified to use verapamil as an afterload-reducing agent in the setting of ventricular dysfunction rather than the conventional impedance-reducing agents. However, this use of verapamil needs to be distinguished from its use in influencing ventricular dysfunction through an indirect means. For example, as with nifedipine and other

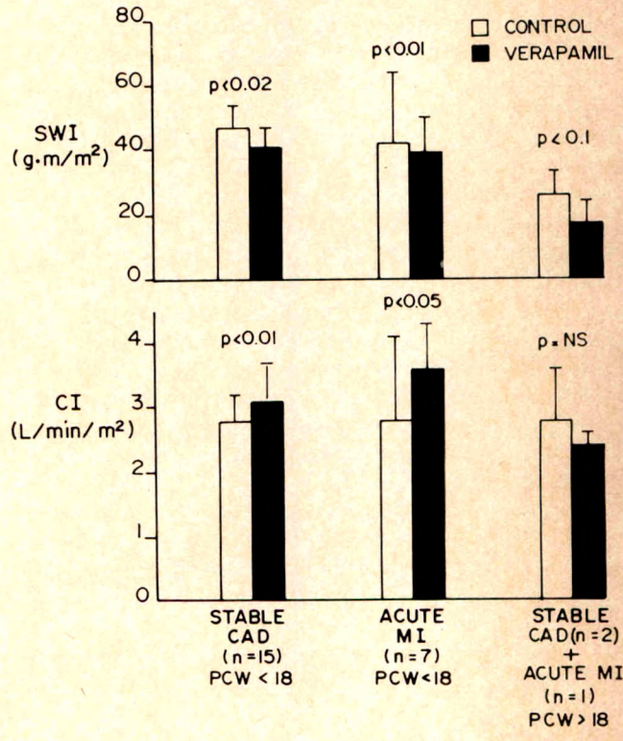

FIGURE 4. Effects of verapamil (0.145 mg/kg intravenously, followed by intravenous infusion of 0.005 mg/kg/min) on stroke work index (SWI) and cardiac index (CI) in patients with varying levels of mean pulmonary capillary wedge pressure (PCW). In patients with significantly increased mean wedge pressure (>18 mm Hg), SWI is significantly decreased by verapamil. In these patients, increases in mean wedge pressure may lead to abrupt clinical deterioration (based on data from Chew et al[13]). CAD = coronary artery disease; MI = myocardial infarction.

calcium antagonists, verapamil has been shown to exert beneficial effects in patients with ventricular dysfunction resulting from myocardial ischemia induced either by exercise[18] or atrial pacing.[19] Similarly, when cardiac failure is either produced or aggravated by development of dysrhythmias responsive to intravenous verapamil, use of the drug in such patients is likely to be associated with improvement rather than deterioration in hemodynamic and ventricular function. Under these circumstances, the hemodynamic improvement that follows the slowing of the heart rate outweighs verapamil's potentially negative inotropic effects.[29] In this context, it is of interest that although most of the patients treated with verapamil for supraventricular tachyarrhythmias by Schamroth et al[30] were in heart failure, an excellent clinical outcome was almost uniformly obtained. Nevertheless, even in this setting caution is warranted because the reversal of an arrhythmia by verapamil is not invariable and profound cardiac depression may result in the absence of a prompt antiarrhythmic response. This is particularly likely in the case of wide QRS tachycardia, a setting in which a ventricular tachycardia may be erroneously mistaken for a supraventricular tachycardia with aberrant conduction.

On theoretical grounds, another clinical situation in which verapamil and other calcium antagonists might be of benefit in the setting of cardiac decompensation is hypertensive heart disease. Although verapamil has been used to control hypertension in patients with angina pectoris,[31] data on the drug's efficacy and safety in the setting of heart failure complicating accelerated hypertension are limited.[32] In one study by Guazzi,[23] 2 hypertensive patients without previous history of heart failure who received verapamil 160 mg orally 3 times daily had paroxysmal nocturnal dyspnea requiring digoxin and diuretics for the control of the resulting heart failure.

Diltiazem: Diltiazem, the least negatively inotropic calcium antagonist in studies of isolated tissues and intact animals,[33] has not been investigated systematically in patients with varying levels of ventricular dysfunction. In our studies of diltiazem in patients with pacing-induced myocardial ischemia,[16] the drug attenuated the decrease in the LV ejection fraction produced by coronary sinus pacing. Under resting conditions, the mean LV ejection fraction was 63%, decreasing to 53% (<0.01) after pacing; diltiazem pacing at an identical heart rate resulted in an ejection fraction of 59%, which was not significantly greater than the pacing value before diltiazem. However, only 1 of 15 patients in the series had significantly decreased LV ejection fraction. In this patient, the ejection fraction of 45% decreased to 42% during atrial pacing; after diltiazem at an identical pacing rate, the ejection fraction decreased to 32%. This decrease was unexplained; in most other patients the expected decrease in the ejection fraction was attenuated by diltiazem. Such a decrease in the ejection fraction, however rare, indicates that diltiazem has the potential to depress myocardial performance. Nevertheless, the intravenous data for the most part are in agreement with the observations after the long-term administration of the drug to patients undergoing treadmill exercise.[19] For example, in 13 patients with coronary artery disease, the LV ejection fraction decreased 15% (from 52 to 44%) during exercise while the patients were taking placebo; in contrast, during diltiazem administration, the corresponding decrease was 10% (58 to 52%), with the resting baseline value being higher than that before the drug was given. Thus at an identical workload, the LV ejection fraction of 52% was significantly greater than the 44% obtained during the placebo phase of the study. In this series, only 3 of the 13 patients had resting LV ejection fractions of <45% (range 31 to 45%), with a mean of 37%. With exercise during placebo administration, it decreased to 32% (−13.5%). With diltiazem before exercise, the LV ejection fraction increased to 43% (+16.2%); with exercise with diltiazem, the corresponding decrease (43 to 34%) of 20.9% was thus higher than that for the entire group of 13 patients in whom the mean LV ejection fraction of 58% with diltiazem at rest decreased to 52% with exercise (a decrease of 10.3%). Thus, although diltiazem may exert a beneficial effect on LV ejection fraction during ischemia, these preliminary data in small numbers of patients suggest that such a salutary effect may be less apparent in the subset of patients with significant ventricular dysfunction. In experimental heart failure after long-term volume loading in the dog,[34] diltiazem has been found to exert significant myocardial depressant effects. A similar depressant effect was not demonstrable for the frequently used afterload-reducing agent nitroprusside, emphasizing the essential difference between conventional impedance-reducing agents and calcium antagonist drugs.

The aforementioned data suggest that ventricular dysfunction resulting from myocardial ischemia may be lessened by the administration of diltiazem. This effect is undoubtedly due in part to the calcium antagonist's favorable effect on the determinants of myocardial oxygen consumption, and, as suggested by data from experimental studies on regional blood flow,[35] possibly on myocardial perfusion as well.

Calcium Antagonists as Afterload-Reducing Agents

The available data on verapamil discussed earlier and the theoretical considerations, as well as anecdotal experience and a preliminary study with diltiazem in a small series of patients with cardiac failure,[36] do not establish the role of these agents in congestive failure. The clinical utility of either compound as an afterload-reducing agent solely for the treatment of cardiac failure caused by irreversibly impaired ventricular function is limited. This question is not yet clearly answered for nifedipine and the newer dihydropyridines. A number of uncontrolled studies with nifedipine in cardiac failure of various origins, although indicating that beneficial hemodynamic effects may follow in some patients, especially over the short term, do not clearly support the use of nifedipine as a primary afterload-reducing agent. In the short-term study by Polese et al,[26] 7 patients with congestive heart failure caused by primary myocardial disease with a mean capillary wedge

pressure of 39 mm Hg, a significant decrease in the pulmonary wedge pressure to 26 mm Hg and an improvement in cardiac index and other indexes of ventricular performance were observed. In this context the data of Elkayam et al[37,38] on the short-term hemodynamic effects of orally administered nifedipine in 32 patients with severe congestive heart failure are of interest. The effects reported were variable, unpredictable and often adverse. For example, although nifedipine functioned as a powerful arterial dilator, often producing an increase in cardiac index, 10 of 32 patients did not respond and 4 developed severe hemodynamic deterioration. Furthermore, the potentially unfavorable effect of nifedipine could not be predicted from baseline hemodynamic features or the LV ejection fraction. Their data cast serious doubt on the role of nifedipine as an afterload-reducing agent in patients with severe chronic congestive cardiac failure.

The subset of patients with cardiac failure that might benefit from the administration of nifedipine is the one with primary valvular regurgitation associated with relatively preserved ventricular ejection function. For example, in patients with aortic and mitral regurgitation and pulmonary edema, single sublingual doses of nifedipine were reported to produce clinical improvement accompanied by decreases in pulmonary wedge pressures and circumferential wall stress, and increases in circumferential fiber shortening, the mean rate of ejection and cardiac index.[26] In patients with chronic congestive cardiac failure (mean LV filling pressure of 19 mm Hg), the hemodynamic improvement after nifedipine appeared to be demonstrable most readily in those with mitral regurgitation,[39] an entity in which afterload reduction by whatever means has been shown to be of much clinical utility. It is noteworthy that in the study by Cantelli et al[39] in this setting, the addition of digoxin plus nifedipine resulted in an even greater augmentation of cardiac performance than with nifedipine alone. We emphasize that although these preliminary, limited data with nifedipine as an afterload-reducing agent in a particular subset of patients with cardiac failure are encouraging, the effects of the drug in this regard must be compared stringently with those of conventional impedance-reducing agents devoid of intrinsic negative inotropic propensity. Only then will the precise role of the dihydropyridine group of calcium antagonists as afterload-reducing agents in the control of chronic congestive heart failure be clearly defined. For the present, the available data indicate that such a role is likely to be limited.

Therapeutic Implications

The data discussed herein suggest that, in patients with relatively preserved ventricular function, the potential intrinsic depressant effect of calcium antagonists is nullified or even reversed by their potent vasodilator actions. With nifedipine, a positive inotropic effect may be seen in association with varying degrees of tachycardia. A significant but clinically negligible degree of negative inotropic effect may be seen with diltiazem and verapamil.

Of the 3 calcium antagonists discussed in this article, the hemodynamic profile of nifedipine appears to be the most favorable for use in patients with depressed ventricular function. However, a clear distinction needs to be made between using this compound to treat a clinical situation for which this class of drugs is normally indicated in a patient with depressed ventricular function, and using it solely to improve cardiac failure by impedance reduction.

In patients with significantly depresed LV function, especially with increased LV filling pressures, clinical deterioration may supervene in a good proportion; such an effect is less likely to occur with nifedipine unless sympathetic reflexes are blocked. However, when heart failure is due to ischemia or hypertension, reversal of these functional abnormalities is likely to lead to improvement rather than deterioration in myocardial function. Similarly, cardiac failure aggravated by tachyarrhythmias is likely to be alleviated if these drugs (especially diltiazem or verapamil) lead to a prompt termination of arrhythmia. Whether calcium antagonists may be used for the purposes of afterload reduction in patients with congestive heart failure is not clear. At least in the case of nifedipine, it has been found that in certain subsets of patients, hemodynamic function may be improved during short-term administration. In others, however, cardiac failure may be aggravated. The overall data do not indicate that, as a class, calcium antagonists are likely to represent an important advance as impedance-reducing agents. Their use in most patients is not accompanied by a significant deterioration in ventricular function, but heart failure may be aggravated in those with severely decreased LV ejection fraction. We recommend caution with respect to the choice of an individual agent as well as the route and dose of drug administration in patients with compromised ventricular performance.

Slow Inward Current and Cardiac Arrhythmias

ROBERT F. GILMOUR, Jr., PhD, and DOUGLAS P. ZIPES, MD

The slow inward current contributes to the normal electrical and contractile activity of several cardiac and vascular tissues and also may mediate the electrical abnormalities responsible for certain cardiac arrhythmias. The slow inward current differs from the fast inward sodium current in that it is carried primarily by calcium rather than sodium, requires a more positive level of membrane potential to be activated, has slower activation and inactivation kinetics, is responsible for normal depolarization in sinus and atrioventricular (AV) nodal cells and is blocked by a rather specific group of agents that includes verapamil, diltiazem and nifedipine. Recent data suggest that slow-channel openings occur in bursts, separated by silent periods, and that less negative membrane potentials and beta-adrenergic stimulation increase the probability that the channels will open. Inactivation of the channels is associated with a lower probability of channel opening. Slow-channel blocking agents such as verapamil, diltiazem and nifedipine appear to bind to activated, rather than rested, slow channels. Therefore, their effects are more prominent at faster pacing rates and at less negative membrane potentials. Clinically occurring cardiac arrhythmias dependent on the slow inward current include primarily sinus and AV nodal reentry and reciprocating tachycardia in the Wolff-Parkinson-White syndrome when one of the pathways incorporates the AV node. Damaged atrial, ventricular and specialized tissue also can generate slow response-mediated reentry or forms of automaticity that may be clinically important under certain circumstances.

(Am J Cardiol 1985;55:89B–101B)

The slow inward current contributes to the normal electrical and contractile activity of several cardiac and vascular tissues and also may mediate the electrical abnormalities responsible for certain cardiac arrhythmias. Abnormalities involving the peripheral and coronary vasculature can affect the genesis of arrhythmias indirectly, whereas abnormalities involving pacemaking, specialized conducting and working myocardial tissues affect the genesis of arrhythmias directly. In this report, we summarize present knowledge concerning the electrophysiologic characteristics of the slow inward current, its modulation by autonomic nervous system neurotransmitters, and its role in cardiac action potential generation and propagation under physiologic and pathophysiologic conditions. We then discuss the possible participation of the slow inward current in the genesis of some cardiac arrhythmias and the therapeutic indications, efficacy and possible mechanism of action of slow-channel blocking agents.

Characteristics of the Slow Inward Current

After the first recordings of transmembrane potentials in cardiac tissue,[1,2] Noble[3] constructed a mathematical model that reproduced the time course of Purkinje fiber action potentials. He assumed that changes in transmembrane potential were due to voltage- and time-dependent alterations in specific membrane conductances to sodium (depolarization) and potassium (repolarization), much as Hodgkin and Huxley[4] had shown previously for the action potential of the squid giant axon. However, other investigators demonstrated that action potential amplitude and duration in guinea pig ventricle were unchanged by lowering extracellular sodium ion concentration ($[Na^+]_o$)[5,6] and the upstroke and plateau phases of various cardiac action potentials could be dissociated in several ways.[7,8] These reports suggested that the currents responsible for the cardiac action potential differed qualitatively, as well as quantitatively, from those previously described in nerve.

Reuter[9] strongly supported this suspicion by demonstrating directly the existence of an inward calcium current in Purkinje fibers using a voltage clamp technique. This current differed from the previously described fast inward sodium current in that it required a more positive level of depolarization to be activated, remained activated for a longer period of time, was not blocked by the sodium-channel blocker tetrodotoxin, depended on the extracellular calcium concentration and had a reversal potential near the expected calcium equilibrium potential. Subsequently, these results have been confirmed by other investigators. It has been proposed that current flow through the slow channel, like that through the fast channel, is regulated by a series of activation and inactivation gates that open and close in response to changes in the transmembrane potential and time, although the actual values for the voltage- and time-dependency of the fast and slow inward currents differ markedly. At a normal resting membrane potential, the slow-channel activation gates are completely closed and the inactivation gates are completely open (Fig. 1). After depolarization of the membrane to a threshold potential, the activation gates open rapidly and the inactivation gates slowly close. Before complete closure of the inactivation gate, current flows through the slow channel. Upon return to the resting potential during diastole, the activation gate rapidly closes while the inactivation gate slowly opens, a process referred to as recovery from inactivation, or reactivation.

Although this scheme has been supported by numerous voltage clamp studies in multicellular preparations, recent experiments in which single calcium channels were studied using a patch clamp technique[10–12] suggest that descriptions of slow-channel activation and inactivation kinetics based on the formulations developed by Hodgkin and Huxley for fast sodium channels may not be appropriate. These experiments indicate that individual calcium channels have a mean open time of approximately 1 ms and that channel openings occur in bursts separated by silent periods. At membrane potentials near threshold, the bursts may occur almost at random and there is a latency between the onset of the clamp and the occurrence of the initial burst. As the clamp potential is made less negative, channel openings tend to occur sooner after the onset of the clamp, and the probability that the channels will open increases, as does the mean burst duration. However, the open time of individual channels is only slightly prolonged and the single channel current magnitude per opening decreases. "Inactivation" of the channels is associated with a lower probability of channel opening, rather than a decrease in current magnitude through those channels that do open. The latency preceding the first channel opening and the bursting patterns of the channels suggest that the calcium channel may cycle through several closed states before opening, in contrast to the first order open-closed reaction typified by the Hodgkin and Huxley scheme.

The threshold potential for activation of the slow inward current generally is from −50 to −35 mV, compared with a threshold potential of −70 to −55 mV for the fast inward sodium current.[13] Therefore, the slow inward current is activated in a membrane potential range at which the fast inward sodium current is largely inactivated. This implies that action potentials ("slow responses") can occur in partially depolarized cells in which the fast sodium channels have been inactivated, provided conditions are appropriate for normal slow channel activation.

It has been estimated that the fast inward sodium current lasts less than 2 ms.[14] Although individual slow channels also appear to open and close rapidly, as discussed previously, the mean current flowing through all of the slow channels in a given cell has a much slower time course, because not all of the slow channels open immediately upon depolarization of the membrane. Rather, some of the slow channels open soon after the membrane is depolarized, whereas others open later. When the currents flowing through the individual channels are averaged over the course of a depolarizing voltage clamp step, the apparent activation of the slow inward current takes from 10 to 20 ms. "Inactivation" may take 50 to 500 ms, depending on the membrane potential,[13] and reactivation takes 2 to 10 times longer than reactivation of the fast sodium channel. Thus, the total slow inward current has a slower onset than the fast inward sodium current, flows for a longer period of time and requires more time after a stimulus to be fully reactivated.

The slow inward current is often referred to as the slow inward calcium current, because the slow channel has been shown to be selectively (but not exclusively) permeable to calcium in various cardiac tissues[15–18] and the calcium-dependence of slow channel current was originally used as one of the discriminating criteria to separate the fast and slow inward currents.[9] Even though the slow channels may be 70 to 100 times more permeable to calcium than to sodium,[17,18] sodium may account for nearly one third of the slow inward current in certain instances, due to the much higher extracellular concentration of sodium versus calcium.

Slow channel current may be carried by other divalent cations, such as barium, strontium, magnesium and manganese,[19–21] although manganese primarily inhibits slow channels in most species. The divalent cations cobalt[20] and nickel[20] and the trivalent cation lanthanum[22] inhibit the slow inward current without being charge carriers themselves. Along with manganese, these latter cations are often used as relatively specific inhibitors of the slow inward current, because they have minimal effects on the fast inward sodium current, although they may have significant direct and indirect effects on outward potassium currents.

Pharmacologic agents such as (−) verapamil[23], its methoxy derivative D-600,[23–25] nifedipine[26,27] and diltiazem[28] can selectively inhibit the slow inward current. The blocking effects of verapamil, D-600 and diltiazem are most apparent at high rates of stimulation and at less negative membrane potentials, implying that these drugs bind to their receptors when the channel is in the open configuration[28,29] and remain bound as the channel inactivates. In contrast, dihydropyridine derivatives

such as nifedipine have been reported to reduce slow-channel conductance without affecting activation or inactivation kinetics.[26] More recent studies have shown, however, that the slow channel blocking effects of the dihydropyridine derivatives are membrane potential-dependent and are more marked at higher stimulation frequencies.[27]

Modulation of the Slow Inward Current by Autonomic Nervous System Neurotransmitters

Neurotransmitters of both the sympathetic[31,32] and parasympathetic[33–35] nervous system modulate the activity of slow channels, as reflected by changes in the slow inward current measured by voltage clamp and by indirect indexes of the slow inward current, such as the configuration of slow channel–dependent action potentials, contractile force, and sinus nodal automaticity and atrioventricular (AV) nodal conduction.

Beta-adrenergic agonists are thought to bind to specific sarcolemmal receptors and activate adenylate cyclase, producing an increase in intracellular levels of adenosine 3′:5′-cyclic monophosphate (cyclic AMP).[36,37] Cyclic AMP activates a cyclic AMP-dependent protein kinase that catalyzes the phosphorylation of specific membrane proteins controlling the permeability of the slow channel, thereby increasing either the number of slow channels available for activation after an appropriate level of depolarization or the probability that an individual channel will be open at any given voltage[11] (Fig. 1). Phosphatase-mediated dephosphorylation and the conversion of cAMP to 5′-AMP by phosphodiesterase deactivates the slow channels. Consequently, inhibition of phosphodiesterase activity increases cyclic AMP levels and the slow inward current.

This scheme is supported by the observations that the slow inward current is increased by catecholamines,[38–40] the lipid soluble dibutyryl derivative of cyclic AMP,[38,39] intracellular application of the catalytic subunit of protein kinase[41] and the phosphodiesterase inhibitor theophylline.[42] In addition, these agents increase the plateau phase of the cardiac action potential,[43,44] increase contractile force,[32,45] produce a positive chronotropic response[46] and restore excitability to cardiac tissues depolarized by high extracellular potassium.[32,47] Agents such as isoproterenol most likely enhance slow channel current by increasing the probability that the channel will open after membrane depolarization, rather than by altering the magnitude of current flowing through the channel.[11]

Muscarinic cholinergic agonists directly inhibit the slow inward current in atria and papillary muscle, as measured by the voltage clamp technique.[34,48] In addition, acetylcholine antagonizes the electrophysiologic effects of β-adrenergic stimulation in ventricular muscle[49] and Purkinje fibers,[33] although it is uncertain whether these effects are due solely to inhibition of the slow inward current. The effects of acetylcholine on the slow inward current may be mediated by an increase in the intracellular concentration of cyclic guanosine monophosphate (GMP), as suggested by an association between increased cyclic GMP levels and decreased force development[50] and shortening of action potential

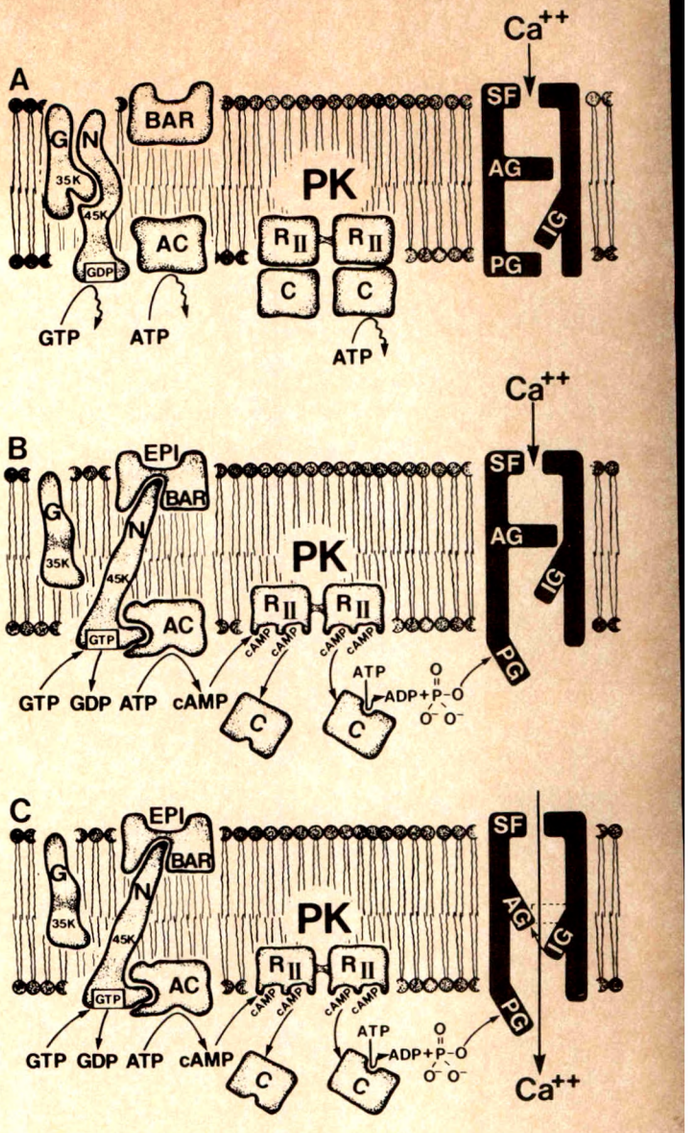

FIGURE 1. A, Hypothetical schematic representation of cardiac sarcolemmal membrane containing β-adrenergic receptor (BAR), G and N subunits of guanine nucleotide regulatory protein, adenylate cyclase (AC), regulatory (R) and catalytic (C) subunits of protein kinase (PK), and slow inward calcium channel, which has filter that is relatively selective for calcium (Ca^{++}) (SF), open inactivation (IG) gate, and closed activation (AG) and phosphorylation-regulated (PG) gates. Structures are shown at resting membrane potential in absence of β-adrenergic stimulation. **B,** binding of β-adrenergic agonist epinephrine (EPI) produces conformational change in β receptor that allows β receptor to interact with regulatory protein. This interaction causes release of GDP from N subunit. Subsequent replacement of GDP with GTP promotes dissociation of N and G subunits, stimulation of adenylate cyclase by N subunit and generation of cyclic AMP (cAMP). cAMP binds to regulatory subunits of PK and liberates catalytic subunits, which phosphorylate a component of slow channel (represented, for simplicity, by a phosphorylation-regulated "gate"). Even though β stimulation causes PG to "open," no current flows through the channel at membrane voltages below excitation threshold, due to persistent closure of activation gate. **C,** after depolarization to membrane voltages greater than threshold, activation gate opens and Ca^{++} flows down its electrochemical gradient into cell. With time, inactivation gate closes (**arrow**) and current flow ceases. On return to resting membrane potential, activation gate closes and inactivation gate reopens. For additional details regarding metabolic and electrical events depicted in this figure, see references 150 and 31, respectively.

duration after intracellular injection of cyclic GMP.[51] However, the electrophysiologic and inotropic effects of acetylcholine have been dissociated from changes in cyclic GMP concentration in several studies.[35,52]

Reduction of the slow inward current by acetylcholine may contribute to the inhibitory effects of parasympathetic stimulation on atrial muscle contractile force,[53] the spontaneous discharge rate of the sinus node[54] and AV conduction.[55] However, acetylcholine also increases outward potassium currents,[34,56] which could contribute importantly to its negative inotropic and chronotropic effects.

Role of the Slow Inward Current in the Normal Electrophysiologic Features of Cardiac Tissues

Action potentials recorded from cells in the sinus nodal region generally arise from maximum diastolic membrane potentials of −70 to −50 mV with a maximum upstroke velocity of <10 V/s[57] (Fig. 2). Action potential amplitude and amount of overshoot past zero membrane potential are less than in myocardial or Purkinje cells and are increased by elevations in $[Ca^{++}]_0$. Slow channel blockers such as manganese[58] and D-600,[59] but not tetrodotoxin,[58,60] reduce sinus nodal spontaneous discharge rate and the action potential amplitude and rate of rise. These observations suggest that the slow inward current mediates the upstroke of the sinus nodal action potential.

The slow inward current of the sinus nodal cell is reduced when $[Ca^{++}]_0$ is lowered.[59] However, even in the presence of tetrodotoxin, a decrease in $[Na^+]_0$ also reduces the slow inward current during voltage clamp and depresses the action potential upstroke,[57] suggesting that the slow inward current in sinus nodal cells may not be a pure calcium current.

Action potentials recorded from the central, or N,[61] region of the AV node also have low resting potential, action potential amplitude, overshoot and upstroke velocity (Fig. 2). They are suppressed by manganese, but not by tetrodotoxin,[62] suggesting that the slow inward current is the predominant depolarizing charge carrier. The low upstroke velocity and excitability of the AV nodal cells are presumed to be responsible for slow conduction and rate-dependent block of the node.[63] Accordingly, AV nodal conduction times and refractory periods are increased by slow channel blocking agents such as verapamil, D-600, manganese and lanthanum.[64]

The slow inward current is believed to contribute importantly to the plateau phase of action potentials recorded from atrial and ventricular myocardium and Purkinje fibers, because the slow inward current is activated at membrane potentials similar to those occurring during the plateau, whereas the fast inward sodium current is largely inactivated at these potentials (Fig. 2).[13,65] Increasing $[Ca^{++}]_0$ would be expected to increase action potential duration due to an increase in the slow inward current. However, action potential duration shortens when $[Ca^{++}]_0$ is increased and prolongs when $[Ca^{++}]_0$ is decreased.[66] In addition, some agents that enhance the slow inward current (such as isoproterenol) increase plateau height and contractile force as expected, but decrease action potential duration of Purkinje fibers. Slow-channel blockers such as D-600 and verapamil reduce the plateau-height of action potentials from myocardium and Purkinje fibers,[67–69] slightly shorten action potential duration in muscle, but prolong total Purkinje fiber action potential duration.

One explanation for this apparent paradox is that repolarizing potassium currents are increased by elevated intracellular calcium levels and are decreased when intracellular calcium levels decrease, as occurs after slow channel blockade.[70,71] A decrease in outward potassium current during blockade of the slow inward current may offset the shortening effects of reduced slow channel current on action potential duration, particularly in Purkinje fibers, and prevent significant changes in refractoriness.

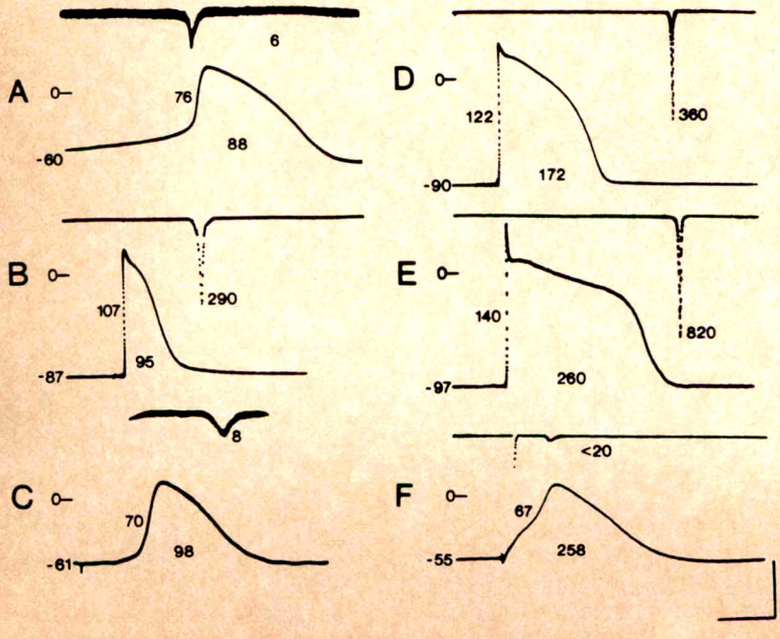

FIGURE 2. Action potentials (**lower recordings**) and dV/dt (**upper recordings**) recorded from various regions of the heart. For each panel, numbers (from **left** to **right**) indicate maximum diastolic potential, action potential amplitude, action potential duration at 90% of repolarization and dV/dt_{max}. **A,** rabbit sinoatrial node. **B,** canine atrial muscle. **C,** rabbit atrioventricular node, **D,** canine ventricular muscle. **E,** canine Purkinje fiber. **F,** diseased human ventricle. Reproduced with permission from Gilmour RF Jr, Zipes DP: Basic electrophysiology of the slow inward current. In: Antman E, Stone P, eds. *Calcium Channel Blocking Agents in the Treatment of Cardiovascular Disorders.* Mt. Kisco, NY: Futura Publishing, 1983: 1–37.

A second explanation is that catecholamines and slow channel blockers affect plateau potassium currents directly.[25,72,73] For example, norepinephrine appears to hyperpolarize cells of the canine coronary sinus[72] and shorten action potential duration of Purkinje fibers[73] by causing a specific increase in potassium permeability. In contrast, slow channel blockers such as verapamil and D-600 decrease outward potassium currents, which correlates with the ability of these drugs to slightly prolong total action potential duration in Purkinje fibers.[25] Slow channel blockers that do not affect plateau potassium current, such as nisoldipine,[74] do not prolong action potential duration.[30]

Role of the Slow Inward Current in Abnormal Electrophysiologic Features of Cardiac Tissues

Propagated action potentials can occur during experimental conditions that largely or completely inactivate the fast sodium current, such as depolarization by elevated $[K^+]_0$ or current passage, low extracellular sodium, or the presence of tetrodotoxin.[8,18,75] Agents that increase the slow inward current, such as catecholamines, histamine, phosphodiesterase inhibitors and fluoride,[43,47] facilitate induction of these slow response action potentials. Slow channel blocking agents such as verapamil,[76] manganese and D-600[77] suppress slow response activity.

Slow responses are characterized by a low upstroke velocity and excitability, slow propagation and prolonged refractoriness. Accordingly, slow responses have been implicated in the production of unidirectional block and slow conduction required for reentrant excitation under experimental conditions in vitro.[78,79] Because many of the experimental manipulations used to elicit the slow response in vitro may occur during myocardial ischemia and infarction in vivo (for example, elevated $[K^+]_0$, generalized cell depolarization, release of catecholamines[80,81]), it has been proposed that slow responses can account for slow conduction and increased refractoriness in ischemic myocardium.[75] However, slow channel blockers such as verapamil and D-600 usually decrease conduction delay and refractoriness during acute myocardial ischemia in vivo.[82] El-Sherif et al[83] have reported that these drugs increase the upstroke velocity and action potential amplitude of slowly rising action potentials recorded from subepicardial preparations isolated several days after coronary artery ligation and studied in vitro. In their study, no action potentials were suppressed by verapamil, suggesting that slow responses did not occur in these preparations. In contrast, fast sodium channel blockers such as tetrodotoxin and local anesthetic agents suppressed action potentials in the subepicardial preparations[83] and often exacerbated ischemia-induced conduction delay in vivo.[82,84]

It appears, therefore, that residual fast inward sodium current may be responsible for depressed action potentials in acutely ischemic myocardium (the so-called depressed fast response) and that the slow inward current may not play a crucial role in impulse initiation or propagation during acute myocardial ischemia. This hypothesis is supported by the observation that depression of cellular electrical activity during acute ischemia, as measured directly with microelectrodes in situ, induces action potentials that are suppressed by tetrodotoxin but not by verapamil[85] (Fig. 3).

In contrast to acutely ischemic myocardium, chronically diseased human atrium often exhibits action potentials having reduced resting membrane potentials, upstroke velocities and amplitudes that are suppressed by verapamil, but not the fast sodium channel blocker procainamide.[86,87] In addition, diseased atrium may exhibit automaticity arising from delayed afterdepolarizations that is enhanced by catecholamines and suppressed by slow channel blockers (verapamil, AHR-2666, acetylcholine), fast channel blockers (tetrodotoxin, lidocaine), and hyperpolarization secondary to increased potassium conductance (acetylcholine).[88] It appears, therefore, that although the ionic basis for abnormal electrical activity in diseased human atrium is complex, the slow inward current may play a role in impulse initiation and propagation.

Slow responses also appear to mediate some types of automaticity and action potentials in chronically diseased human ventricular myocardium.[89–92] Several

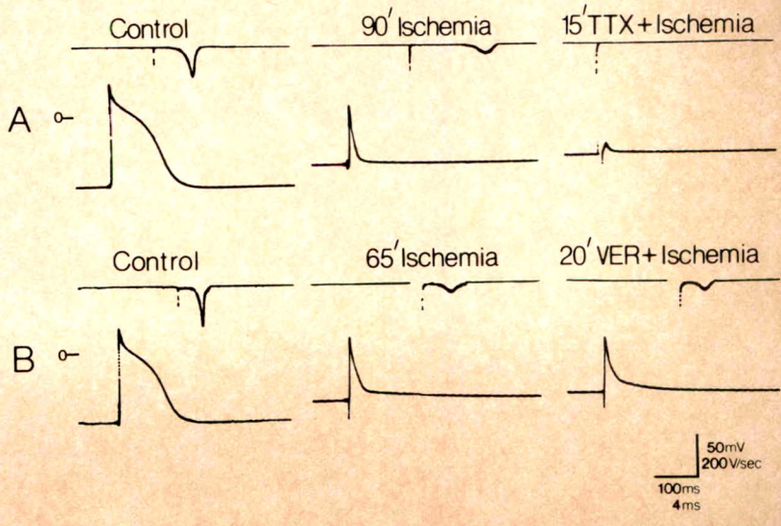

FIGURE 3. Effects of ischemia and ischemia + (TTX) **A** or + verapamil **B** on dV/dt_{max} (upper recordings) and action potential configuration (lower recordings) of atrial transplant cells. After 90 minutes of ischemia, transplant cell **A**, was exposed to TTX (10^{-5} M) for 15 minutes. TTX progressively decreased action potential amplitude and dV/dt_{max} and cell became inexcitable. After 65 minutes of ischemia in another atrial transplant **B**, action potential configuration was similar to that seen at 90 minutes of ischemia in A. Exposure of this cell to verapamil (2×10^{-6} M) for 20 minutes did not produce inexcitability. Reproduced with permission from *Circ Res*.[85]

investigators have recorded action potentials with slowly rising upstrokes and prolonged refractoriness that are suppressed by verapamil and D-600, but not by tetrodotoxin. The resting potential, action potential amplitude and upstroke velocity of these cells are increased by elevated $[Ca^{++}]_0$ and decreased by low $[Ca^{++}]_0$.[91] However, tetrodotoxin and lidocaine reduce the amplitude of some depressed action potentials, suggesting that partially inactivated fast sodium channels may still be capable of initiating action potential upstrokes in some cells.[89,92]

Various forms of abnormal automaticity have been described in diseased human ventricle. Several forms arise from delayed afterdepolarizations or from levels of membrane potential at which the fast inward sodium current is normally inactivated.[89,90] These types of automaticity generally are enhanced by catecholamines, suppressed by verapamil and only occasionally suppressed by tetrodotoxin.[89,90]

Triggered activity arising from delayed afterdepolarizations (also called oscillatory afterpotentials[93]) has also been produced experimentally, most notably by exposure to toxic concentrations of cardiac glycosides,[93,94] and by interventions that favor increased calcium uptake, such as superfusion with solutions containing catecholamines, elevated $[Ca^{++}]_0$ and reduced $[K^+]_0$.[75,95,96] In contrast to most forms of automaticity, triggered activity is accelerated, rather than suppressed, after overdrive pacing. Triggered sustained rhythmic activity occurs in apparently normal atrial myocardium,[85,88] upper pectinate muscles bordering the crista terminalis[97] and mitral valve fibers[98,99] as well as in diseased atrium[88] and ventricle.[89,90,100] Low $[Ca^{++}]_0$ (and, therefore, low $[Ca^{++}]i$) or slow channel blockade with verapamil, AHR-2666 and manganese[93,94,98] suppress delayed afterdepolarizations. Therefore, the slow inward current may modulate the amplitude of delayed afterdepolarizations, despite the fact that the afterdepolarizations can occur at membrane potentials 30 to 50 mV negative to the threshold voltage for the slow inward current. Recent evidence indicates that calcium entry through the slow inward current contributes to oscillatory release of calcium from intracellular stores and a subsequent change in membrane conductance. This permits flow of a small depolarizing current, probably carried by sodium.[96,101] Voltage clamp studies suggest that the oscillatory transient inward current responsible for delayed afterdepolarizations may be a physiologic component of cardiac cellular electrical activity, becoming more prominent when intracellular calcium levels are increased.[101] Induction of the transient inward current also may be facilitated by an increase in $[Na^+]i$, such as occurs after inhibition of the sodium-potassium pump, because increased $[Na^+]i$ increases $[Ca^{++}]i$ through a sodium/calcium exchange.[102,103]

Induction of the transient inward current after increase of [Na]i and $[Ca^{++}]i$ may explain the sensitivity of delayed afterdepolarizations to changes in calcium flux, as well as their depression by decreases in $[Na^+]_0$[104] and exposure to tetrodotoxin[94,99] and lidocaine.[94,105] Spontaneously occurring or epinephrine-induced delayed afterdepolarizations in human atrium are not suppressed by tetrodotoxin or lidocaine, however, raising the possibility that mechanisms for triggered activity under various circumstances may differ.[88]

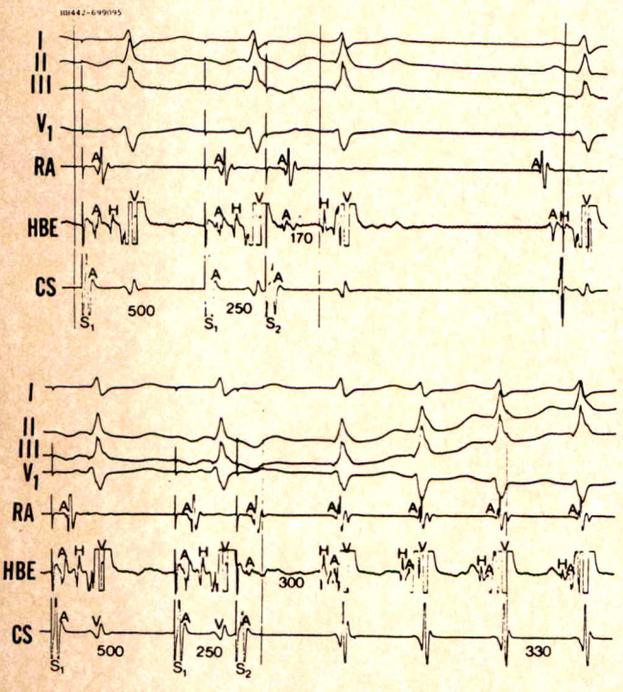

FIGURE 4. Initiation of supraventricular tachycardia in patient with dual atrioventricular (AV) nodal pathways. The panels show last 2 paced beats (S_1) of train delivered to coronary sinus at pacing cycle length of 500 ms. Results of premature atrial stimulation at an S_1-S_2 interval of 250 ms on 2 occasions are shown. In **top panel,** S_2 was conducted to ventricle with an AH interval of 170 ms. In the **bottom panel,** S_2 was conducted with an AH interval of 300 ms, followed by AV nodal reentry. CS = coronary sinus electrogram; HBE = His bundle electrogram; RA = right atrial electrogram; I, II, III, V_1 = scalar electrocardiographic leads. Reproduced with permission from *Circulation.*[109]

The Slow Inward Current and Cardiac Arrhythmias: Supraventricular Tachycardias, Atrioventricular Nodal Supraventricular Tachycardias

The weight of evidence implicates reentry as the mechanism responsible for initiation and maintenance of AV nodal supraventricular tachycardias (SVTs) and places the site of the anterogradely conducting pathways in the AV node where conduction is slow channel-dependent. The site of the retrogradely conducting pathway, as well as the geometry and electrophysiologic features of its fibers, are still being defined and may not be the same for all patients with AV nodal reentrant SVT (Fig. 4).

Verapamil or diltiazem, administered intravenously, has been shown to terminate effectively episodes of AV nodal reentrant SVT in patients.[106–112] Slow channel blockers administered orally may produce similar results. Generally, the slow channel blockers terminate AV nodal reentrant SVTs by causing prolongation and eventual block of anterograde AV nodal conduction.[109] This may be analogous to experiments in an isolated rabbit AV nodal preparation in which verapamil prevented AV nodal reentry and initiation of atrial tachy-

cardia by causing premature atrial impulses to block rather than to conduct with the delay needed to initiate reentry.[113] Verapamil primarily (but not exclusively[114]) affects conduction and refractoriness in the anterogradely conducting pathway, exerting no significant effect on the pathway used for retrograde conduction during the SVT[112] (Fig. 5 and 6). This observation lends further credence to the concept that, at least in some patients with AV nodal reentrant SVT, the retrogradely conducting pathway may not be composed of typical AV nodal fibers.[115,116]

Supraventricular Tachycardia Related to Wolff-Parkinson-White Syndrome

Reciprocating tachycardia in the Wolff-Parkinson-White (WPW) syndrome most often involves conduction over the AV node anterogradely, and thus involves slow channel–dependent fibers in this portion of the reentrant loop.[117] The remaining fibers in the reentrant pathway, atrium, ventricle or accessory pathway are normally fast channel–dependent.

Verapamil exerts no significant direct electrophysiologic effects on the accessory pathway (Fig. 7) and terminates SVT in patients with WPW syndrome by slowing and blocking conduction over the normal AV node.[109,112] Thus, after verapamil administration, reciprocating tachycardia in the WPW syndrome most often terminates during anterograde[118] conduction due to AV nodal block. If verapamil does not produce block in the AV node during SVT, the tachycardia continues at a slower rate, resulting from prolongation of AV nodal conduction time. Verapamil may actually produce faster ventricular rates during atrial fibrillation in patients with WPW syndrome, probably due to reflex sympathetic stimulation in response to peripheral vasodilation and transient hypotension, shortening the refractory period of the accessory pathway.[109,119] Verapamil has been incriminated in precipitating ventricular fibrillation after administration to a patient with atrial fibrillation.[120] Intravenous verapamil should not be given to patients who have WPW syndrome and atrial fibrillation. Oral verapamil does not appear to generate the same risk of increased ventricular rate during atrial fibrillation and probably could be used if indicated.

Some data suggest that the AV node in patients with WPW syndrome may conduct more rapidly and exhibit a shorter refractory period than in patients with SVT unrelated to the WPW syndrome.[121] Verapamil appears

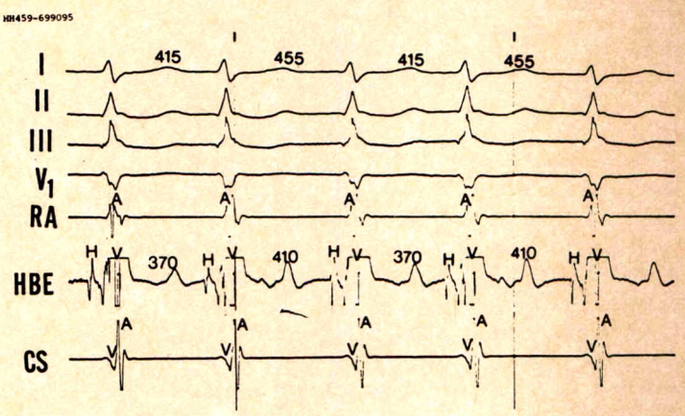

FIGURE 5. Same patient as in Figure 4. After intravenous verapamil administration, supraventricular tachycardia developed cycle length alternans of 40 ms, caused by alteration in AH intervals. The HA interval, HV interval and atrial activation sequence remain constant. Reproduced with permission from *Circulation.*[109] Abbreviations as in Figure 4.

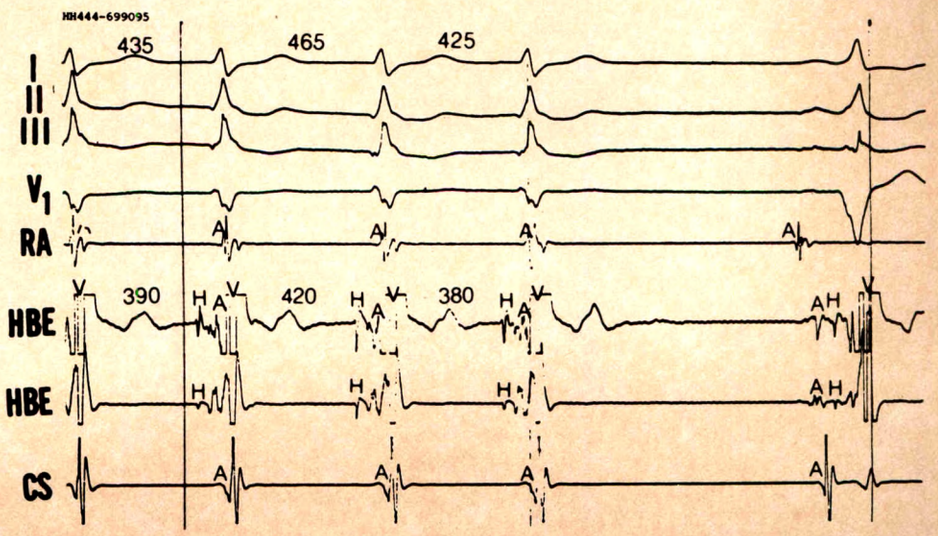

FIGURE 6. Same patient as in Figures 4 and 5. Supraventricular tachycardia terminated because of block of atrial depolarization proximal to His bundle recording site. Reproduced with permission from *Circulation.*[109] Abbreviations as in Figure 4.

to prolong the AV nodal conduction time and the functional and effective refractory periods of the AV node to a lesser extent in patients with WPW who have SVT, than in patients who have SVT due to AV nodal reentry.[109] The reason for the reduced electrophysiologic response of the AV node to verapamil in patients with WPW syndrome is unknown.

Sinus Nodal Reentry

Premature stimulation can produce slow propagation in the sinus node, block in some areas, and the development of repetitive responses, most likely owing to reentry. Evidence from a number of studies in man[122–124] and animals[125,126] supports the concept that sustained reentry in the sinus node can occur and cause SVT. Recently, Allessie and Bonke[125] showed that the reentrant circuit in the isolated rabbit preparation was located entirely within the sinus node and that the atrium was not an essential link. This observation suggests that slow channel–dependent tissue may comprise the critical portion of the reentrant circuit.

SVTs thought to be due to sinus nodal reentry generally have a slower rate than SVTs due to AV nodal reentry or reentry over an accessory pathway, although significant overlap exists. P waves appear in front of the QRS complex and exhibit a contour similar to the P wave during sinus rhythm, with the expected sequence of activation beginning in the upper right atrium and progressing caudally (Fig. 8).

The effects of verapamil in patients with SVT from sinus nodal reentry have not been investigated systematically. Verapamil given intravenously to dogs appeared to exert a differential response on the sinus and AV nodes.[127] Verapamil prolonged AV nodal conduction time and produced AV block at plasma concentrations that did not significantly alter the spontaneous discharge rate of the sinus node. Verapamil's effect on conduction within the sinus and AV nodes was not compared. Similar observations have been made in man.[128] When given after β-adrenergic blockade, verapamil achieves more significant depression of sinus nodal automaticity. It is possible that a reflex increase in sympathetic tone prevents verapamil, when given alone intravenously, from significantly altering sinus nodal automaticity.[129]

Curry and Krikler[122] found that verapamil promptly terminated SVT due to sinus nodal reentry in 2 patients and prevented reinitiation of the tachycardia in 5. We have given verapamil to 2 patients with SVT caused by AV nodal reentry and sinus nodal reentry.[109] In both patients, the SVT caused by sinus nodal reentry persisted several minutes after verapamil had terminated the AV nodal reentrant SVT. It would appear that the sinus nodal reentrant SVT resisted the suppressing effects of verapamil more than did the AV nodal reentrant SVT. In fact, in the second patient, verapamil may have even caused the sinus nodal reentrant SVT, which could not be produced before verapamil administration, by initiating partial conduction delay in the sinus node.

Atrial Reentry

Reentry within the atrium, unrelated to the sinus node, has been shown experimentally to occur in the rabbit[130] and dog[131] atrium, with or without an anatomic obstacle, and may be a cause of SVT in man. Examples of SVT purported to be due to atrial reentry have been cited,[124,132,133] but their relative infrequency in published reports suggests it is not a common cause of SVT in man. Atrial reentry differs from sinus nodal reentry by a P-wave morphology and atrial sequence of activation unlike that found during sinus rhythm. Distinguishing atrial tachycardia owing to automaticity from atrial tachycardia sustained by reentry over very small areas (micro-reentry) is very difficult; therefore, conclusions regarding electrophysiologic mechanisms of this SVT based on presently available information must be accepted cautiously.

It can be speculated that verapamil might terminate SVT if it were due to reentry over diseased atrial fibers that were slow channel–dependent. To our knowledge,

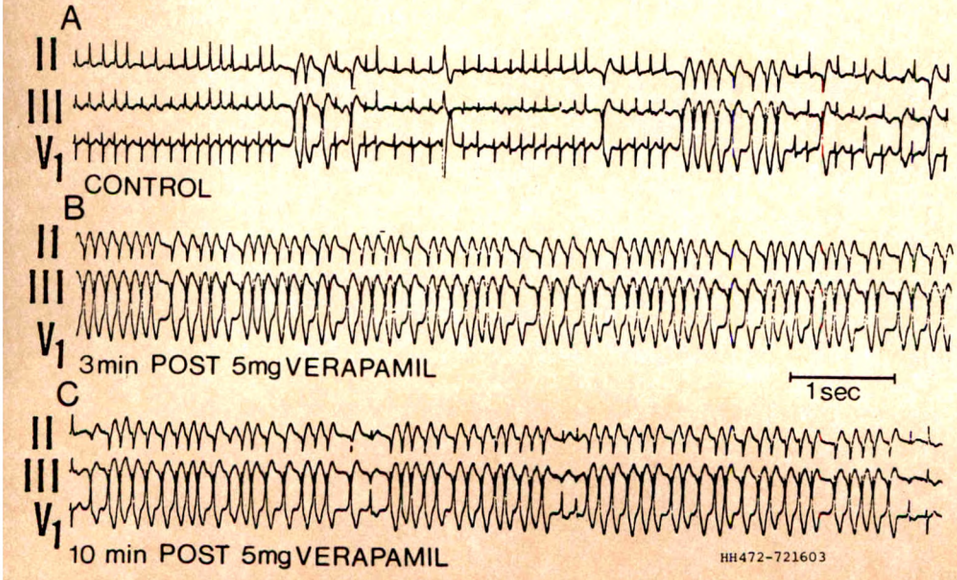

FIGURE 7. Effect of verapamil on ventricular activation during atrial fibrillation in patient with Wolff-Parkinson-White syndrome. Tracings were recorded before and 3 and 10 minutes after verapamil administration. Increase in ventricular rate and increased number of preexcited ventricular complexes occurred 3 minutes after verapamil administration. Effect diminished at 10 minutes. Reproduced with permission from *Circulation*.[109]

however, no information exists regarding the clinical effects of verapamil on SVT caused by atrial reentry. In experimentally induced reentrant atrial tachycardia in the rabbit, verapamil exerted no significant effects.[134]

In man, SVTs characterized as automatic by a variety of criteria have been described,[133,135–137] but most of these are incomplete. Their differentiation from other forms of SVT, such as sinus nodal reentry (if the P wave of the automatic atrial tachycardia resembles the sinus-initiated P wave) or atrial reentry (particularly if caused by micro-reentry), may be difficult. However, in view of the experimental findings of triggered activity from a variety of atrial fibers, including human mitral valve, it is possible that such triggered activity occurs in man. Triggered activity has been demonstrated in isolated preparations of the mitral valve, coronary sinus and normal and diseased atria. Suppression of such activity by verapamil suggests but does not prove that the slow inward current may play a role in the genesis of this triggered activity. At present, however, the meager clinical information does not support the conclusion that such verapamil-suppressed triggered activity is responsible for many clinically occurring atrial tachycardias.

We have performed electrophysiologic studies on several patients who had SVT that met previously established criteria for automaticity.[109] The responses of automaticity in these patients to various pacing protocols were not characteristic of triggered activity. Verapamil resulted in a decrease in the ventricular response to the atrial tachycardia without suppression of the tachycardia (Fig. 9).

Nonparoxysmal Atrioventricular Junctional Tachycardia

Nonparoxysmal AV junctional tachycardia is often due to cardiac surgery, acute rheumatic heart disease, digitalis intoxication or myocardial infarction.[138] Sometimes no origin can be discovered and the patient may be otherwise healthy. Conversely, nonparoxysmal AV junctional tachycardia at very rapid rates has been described in 4 children, and was found to be a very serious, difficult-to-control SVT.[139] The mechanism responsible for nonparoxysmal AV junctional tachycardia is generally assumed to be enhanced automaticity for the His bundle or a contiguous structure that possesses automatic activity. In some instances, it is possible that nonparoxysmal AV junctional tachycardia originates in small groups of atrial fibers that have a mass insufficient to generate a P wave that can be recorded on a scalar ECG. In such instances, careful mapping during an invasive electrophysiologic study is necessary to find the area of atrial depolarization.[140] Wenckebach periods may occur, but the presence of exit block has not yet been demonstrated clinically, and the block may be in the AV node, with the origin of the nonparoxysmal AV junctional tachycardia proximal to the site of His bundle recording. In an interesting study of accelerated junctional escape beats, shorter junctional escape intervals were observed after premature atrial complexes, thus raising the possibility of overdrive acceleration in these fibers. Pacing studies and the effects of verapamil were not tested.[141]

Clinical information regarding the effects of slow channel blockers on nonparoxysmal AV junctional tachycardia is negligible. Automaticity in the His bundle is generally thought to be similar to that found in Purkinje fibers and therefore not slow channel-dependent. However, it is certainly possible that some of the interventions responsible for nonparoxysmal AV junctional tachycardia may create conditions in which the slow inward current is operative.

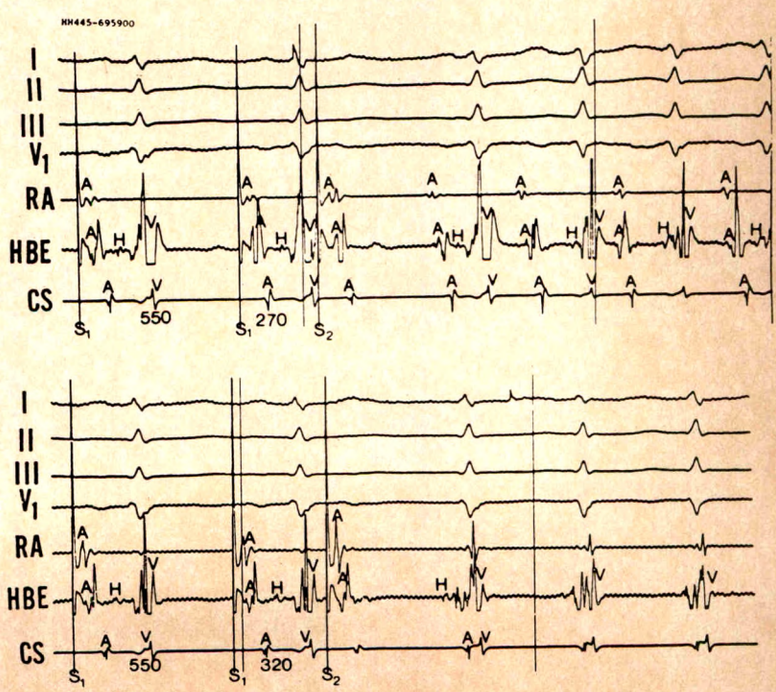

FIGURE 8. Initiation of atrioventricular (AV) nodal and sinus nodal reentrant tachycardias. In **top panel,** premature stimulation of high right atrium at S_1-S_2 interval of 270 ms initiated atrial tachycardia with activation sequence similar to that occurring during high right atrial pacing. In **bottom panel,** premature stimulation of right atrium at S_1-S_2 interval of 320 ms resulted in prolonged AH interval and initiated AV nodal reentry. Retrograde low right atrial activation occurred before ventricular activation and was followed by left (coronary sinus) and high right atrial activation. Reproduced with permission from *Circulation.*[109]

Atrial Flutter and Atrial Fibrillation

Whether reentry or automaticity or both is responsible for atrial fibrillation is still unknown.[142] Much evidence supports the role of reentry as a cause of atrial flutter,[143] but abnormal automaticity cannot be excluded.[131] Because sustained atrial flutter or atrial fibrillation occurs infrequently in patients without heart disease, it is possible that the atria in these patients manifest abnormal electrophysiologic characteristics, some of which may be consistent with slow channel–dependent action potentials.[88] At present, however, insufficient data prevent any definite conclusions.

Verapamil reportedly converts approximately 30% of episodes of atrial flutter and 16% of episodes of atrial fibrillation to sinus rhythm.[144] Based on our own studies, we think these data may be optimistic. The consistent effect of verapamil in patients with atrial flutter or atrial fibrillation (without WPW syndrome) is a prompt decrease in the ventricular response, lasting at least 30 minutes[109] (Fig. 10).

In some patients with atrial flutter or atrial fibrillation, the slow response may play a role in the genesis and maintenance of the arrhythmias. However, this con-

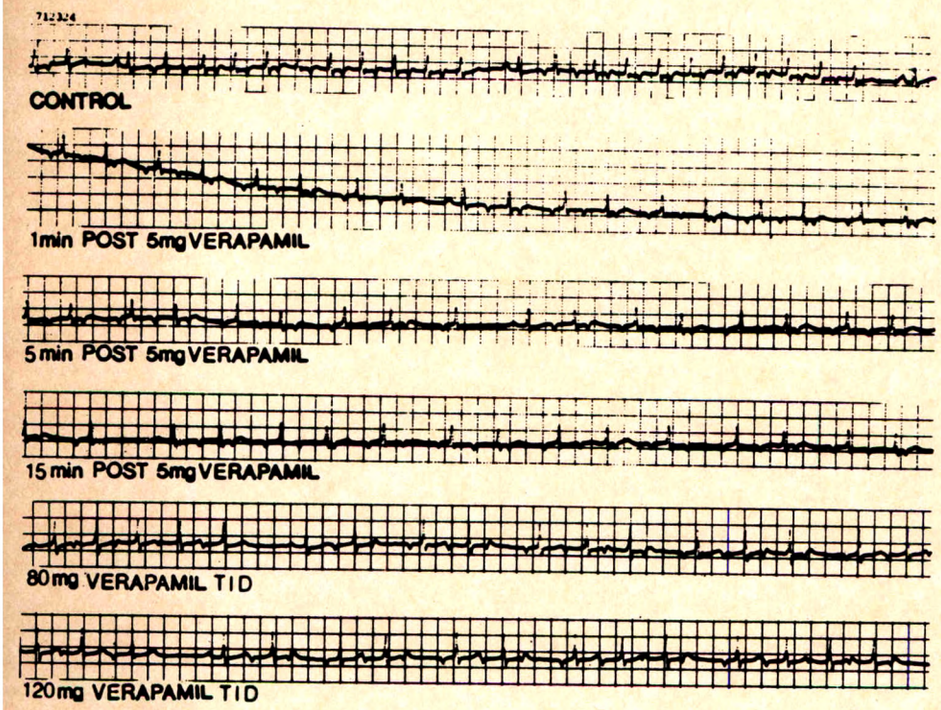

FIGURE 9. Effects of intravenous and oral verapamil in patient with ectopic (presumed automatic) atrial tachycardia. Note that verapamil produced slight slowing of discharge rate of atrial tachycardia and primarily caused reduction in ventricular response. Reproduced with permission from Zipes DP, Gilmour RF Jr. Calcium antagonists and their potential role in the prevention of sudden coronary death. In: Greenberg, HM, Dwyer EM Jr, eds. Sudden Death. Ann N Y Acad Sci 1982;382:258–288.

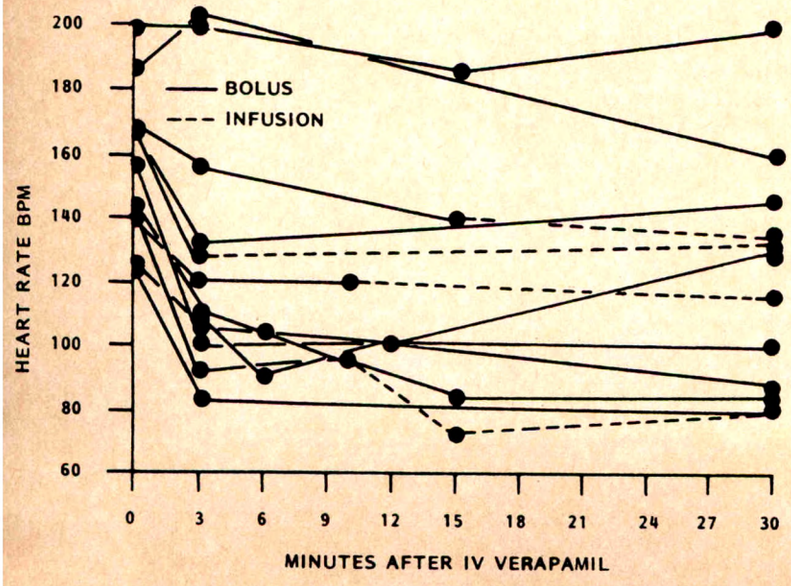

FIGURE 10. Response of atrial fibrillation after intravenous verapamil administration. Heart rate in beats per minute (BPM) is plotted against time in minutes after intravenous administration of verapamil. **Solid lines** indicate response after bolus injection and **dashes** indicate intravenous infusion. Mean ventricular response was reduced to 81.6% of control rate at 3 minutes ($p < 0.01$). After maximal response, ventricular rate tended to increase slightly. Reproduced with permission from *Circulation*.[109]

clusion is based on consideration of in vitro observations of transmembrane potentials recorded from diseased human atrial fibers.[88] No clinical information is available to support the importance of the slow inward current in these SVTs.

Ventricular Tachycardia

Although it is quite clear from experimental studies that the slow response can be created and demonstrated in a variety of preparations of ventricular fibers, it is not at all clear whether the slow response can be related causally to the genesis of ventricular tachycardia in man. Only a few noncontrolled studies of the response of ventricular tachycardia to slow channel blockers have been reported in a small number of patients, and the data are inconclusive.[111,145] Generally, verapamil has not been very effective in terminating ventricular tachycardia, although exceptions have been reported.[146–148] In 1 report, the mechanism of ventricular tachycardia may have been triggered activity.[149] Thus, preliminary data suggest that the slow response may not be important in the genesis of most ventricular tachycardias and that the slow channel blockers may not be as effective in treating ventricular tachycardia as they are in treating SVT.

In summary, observations from experimental and clinical studies suggest that slow channel blocking agents may suppress arrhythmias requiring slow channel–dependent tissues for their initiation or perpetuation. Most often, these arrhythmias include sinus and AV nodal reentrant tachyarrhythmias and reciprocating tachycardia in the WPW syndrome when 1 of the pathways involves the AV node. Damaged atrial and ventricular tissue also may generate slow response–mediated automaticity, triggered activity and reentry under certain circumstances. The clinical importance of triggered activity remains to be established. The contribution of slow responses to arrhythmia development in vivo is uncertain, however, because the available experimental and clinical data indicate that many supraventricular and ventricular arrhythmias are not suppressed by slow channel blockers. Although preliminary reports suggest that such agents as verapamil or diltiazem do not appear to be particularly effective for the treatment of ventricular tachycardia, they do have diverse actions on autonomic receptors, vascular tone and myocardial metabolism that could make them useful for the prevention of sudden death. This and many other potential actions of this novel class of drugs remain to be investigated.

Calcium-Entry Blocking Agents in the Treatment of Systemic Hypertension

BRIAN F. ROBINSON, MD

Calcium-entry blocking agents resemble established dilators such as diazoxide, minoxidil and hydralazine in that they act predominantly on the arterial resistance vessels and have little or no effect upon the veins. They have therefore been evaluated in the treatment of hypertension. Controlled studies have shown that verapamil and nifedipine are effective in decreasing blood pressure when given as sole agents. The antihypertensive effect of nifedipine is additive with that of a β blocker, and nifedipine is also effective when given as a "third step" agent in combination with a β blocker (or α methyldopa) and a diuretic. In contrast to other directly acting dilators, nifedipine causes, at most, only moderate stimulation of renin secretion and verapamil does not increase renin release at all; neither drug induces sodium retention. Both verapamil and nifedipine produce a moderate incidence of unwanted effects; these are mostly subjective in nature, but verapamil may cause constipation that is occasionally severe and nifedipine sometimes causes ankle swelling. Calcium-entry blockers should be considered as initial therapy when some contraindication exists to the use of other standard drugs. Nifedipine appears preferable to hydralazine for use in combination with a β blocker and a diuretic: it is at least as effective as hydralazine and has a lower incidence of serious adverse effects.

(Am J Cardiol 1985;55:102B–106B)

The peripheral dilators such as hydralazine and diazoxide that have proved effective in the treatment of hypertension differ widely in their chemistry and basic mechanism of action, but they all share 1 common characteristic: they act predominantly upon arteriolar resistance vessels and have little or no effect on veins.[1] The observation that calcium-entry blocking agents such as verapamil[2] and nifedipine[3] also act selectively on the resistance vessels suggested that they too might be particularly suited to the treatment of hypertension. It was therefore decided to evaluate the effectiveness of these drugs in patients attending the hypertension clinic of this hospital; over the past 5 years more than 100 men and women have been treated as outpatients with nifedipine and, more recently, verapamil. It is against this background that the effectiveness of the calcium-entry blocking agents will be evaluated and an attempt made to assess their likely role in the treatment of hypertension.

After early uncontrolled observations on the blood pressure-decreasing effect of verapamil, its antihypertensive action was subsequently confirmed in controlled trials,[4,5] and the antihypertensive action of nifedipine was also demonstrated.[6] In recent years, the effectiveness of the calcium-entry blocking agents in the treatment of hypertension has been systematically investigated and it has become clear that drugs of this class are able to induce a sustained decrease in arterial pressure, both when given alone and also when given in combination with other standard agents.

Effectiveness of Calcium-Entry Blocking Drugs as Antihypertensive Agents

Use as sole therapy: The antihypertensive action of both verapamil and nifedipine has been assessed in studies using continuous 24-hour intraarterial blood pressure recording. In 16 patients studied in this way, verapamil, in a dosage of 120 to 160 mg 3 times daily decreased average daytime pressure from 180/95 to 158/79 mm Hg ($p < 0.001$); heart rate decreased significantly by about 10 beats/min.[7] In a similar study by the same investigators, nifedipine slow-release tablets given twice daily in a total daily dose of 40 to 120 mg decreased supine arterial pressure in 17 patients from an average of 175/98 to 141/80 mm Hg ($p < 0.001$) and approximately the same decrease in pressure was maintained throughout the 24 hours; heart rate was not significantly

changed.[8] A study by another group in which nifedipine capsules were given in a dosage of 10 to 20 mg 3 times daily yielded similar results.[9] In all 3 studies the normal circadian rhythm of arterial pressure, with a decrease in the night hours and a relatively rapid increase in the early part of the morning, was maintained during drug therapy.

When taken in capsule formulation, nifedipine is rapidly absorbed, and absorption is even more rapid if the capsule is bitten into and the contents are retained beneath the tongue. The drug has therefore been used in those uncommon circumstances when patients present with severe hypertension and rapid decrease in pressure appears indicated. In a study of 17 patients with severe primary hypertension who were not receiving any other therapy, the short-term effects of 10 mg of nifedipine were measured by full hemodynamic monitoring.[10] Maximal circulatory effect was achieved within about 30 minutes of oral administration to the fasting subjects and within 15 to 20 minutes of sublingual dosage. The maximal decrease in mean arterial pressure averaged 36 mm Hg (−24%); heart rate increased by 22% and cardiac output by 31% ($p < 0.01$). In 3 patients with hypertensive encephalopathy and acute left ventricular failure, arterial pressure decreased from an average of 307/164 to 237/115 mm Hg within 15 minutes; another 10 mg of nifedipine was given after 1 hour and blood pressure decreased progressively to an average of 176/89 mm Hg over the next hour.

In a recent study of 10 patients who presented with "hypertensive crisis" and impaired renal function, nifedipine, 10 to 20 mg sublingually, decreased arterial pressure within 1 hour from 211/134 to 172/107 mm Hg ($p < 0.001$); heart rate increased from 83 to 98 beats/min.[11] In the 7 patients who had evidence of encephalopathy, the signs of this complication subsided. Verapamil is absorbed more slowly than nifedipine and must therefore be given parenterally if rapid action is required; 5 to 10 mg given slowly intravenously was reported to be consistently effective in decreasing arterial pressure when it is acutely increased.[12]

Use in Combination With a Beta-Adrenoceptor Antagonist or Alpha Methyldopa

The depressant effect of verapamil on the atrioventricular node may lead to the development of heart block or other serious rhythm disturbance if it is given intravenously to patients who have already received a β-adrenoceptor antagonist. The risk of such adverse effects is small with oral administration, but it is not negligible,[13] and the possibility of this interaction has deterred physicians from using the combination in the treatment of hypertension. Nifedipine has no significant effect upon the conducting system and can safely be given with a β blocker. The antihypertensive effects of the 2 types of drugs have been shown to be clearly additive. In a single-blind study of 12 hypertensive men, metoprolol (100 mg twice daily) and nifedipine (10 mg 3 times daily) were given either alone or in combination. Supine arterial pressure averaged 178/99 mg Hg with placebo, 158/88 mm Hg with nifedipine, 156/92 mm Hg with metoprolol and 141/84 mm Hg with the combination of the 2.[14] The decrease in pressure induced by the 2 drugs separately and the additional decrease that resulted when nifedipine was added to metoprolol were significant ($p < 0.05$). In an open trial involving 17 patients, similar results were obtained with the combination of propranolol and nifedipine.[15]

Nifedipine has also been used in combination with α methyldopa; in a placebo-controlled trial, the 2 drugs were shown to have additive effects in decreasing arterial pressure.[16]

Calcium-Entry Blocking Agents Combined With Diuretics

It is not yet clear to what extent calcium-entry blockers can usefully be combined with diuretics. In several studies using verapamil, thiazide diuretics were given concurrently,[5,17] but there has been no systematic investigation of the extent to which the antihypertensive effects of the 2 classes of drugs may be additive. Clinical experience suggests that, in some patients at least, a diuretic can cause a further decrease in pressure when added to verapamil and also when added to the combination of nifedipine and a β blocker.

Calcium-Entry Blockers as Third Step Agents

Nifedipine is frequently effective when added to the combination of a β blocker and a diuretic. In a double-blind, placebo-controlled trial carried out in this department, we examined the effect of adding nifedipine (30 to 60 mg daily in divided doses) to the combination of a β blocker and a diuretic. Arterial pressure decreased significantly by 19/11 mm Hg supine ($p < 0.025$) and 21/12 mm Hg standing ($p < 0.05$); heart rate and body weight showed no significant change.[18] In a similar study in which nifedipine at 3 dose levels (30, 60 and 90 mg/day) was added to atenolol (100 mg/day) and bendrofluazide (5 mg/day), a dose-dependent decrease in arterial pressure was observed; the maximum reduction was 23/16 mm Hg supine and 24/19 mm Hg standing ($p < 0.001$).[19] In an open study of 20 patients in whom hypertension was inadequately controlled by the combination of a β blocker, diuretic and vasodilator (mainly hydralazine), the substitution of nifedipine for the vasodilator resulted in a decrease in arterial pressure averaging 25/11 mm Hg supine; the results of this open trial were not analyzed statistically.[20]

The effectiveness of nifedipine when added to the combination of a β blocker and diuretic is thus well established, and the decrease in blood pressure that is achieved appears broadly comparable to that reported with hydralazine.[21] Some patients who are resistant to hydralazine respond well to nifedipine[18,20]; the reverse may also be true, but has not yet appeared in a published report.

Mechanism of Action of Calcium-Entry Blocking Agents in Hypertension

As with other dilator agents, verapamil and nifedipine decrease arterial pressure by relaxing the vascular smooth muscle of the arterioles and so decreasing peripheral resistance. The forearm resistance vessels of patients with primary hypertension are, however, more

sensitive to the dilator action of verapamil than those of normal subjects.[22,23] The enhanced responsiveness to verapamil is believed to reflect increased activity of the potential-operated calcium channels. It has been postulated that this abnormality is a basic functional disorder underlying the increased peripheral resistance.[24] It may therefore be that calcium-entry blocking agents decrease peripheral resistance by specifically reversing the functional abnormality that is maintaining the hypertensive state. If this were so, drugs of this class should be more effective in decreasing blood pressure in patients with hypertension than in normal subjects. This has been claimed for short-term administration of nifedipine,[25,26] but the same may be true of some other antihypertensive agents. If calcium-entry blockers act by specifically reversing pathologically augmented tone, then they should also restore a more physiologic balance of resistances in different beds than would be the case with nonspecific dilators. There is, as yet, no evidence for or against this view.

Effect on Plasma Renin Activity and Sodium Excretion

Short-term administration of nifedipine leads to an increase in plasma renin activity.[27] During long-term administration, nifedipine may induce an increase in renin secretion in some patients, but on average, plasma renin activity has either been unchanged[9] or has shown a statistically insignificant increase.[14,28] Verapamil causes no increase in plasma renin activity during either short-[29] or long-term therapy.[17,29] These effects contrast with those of dilators such as diazoxide and hydralazine, which consistently induce substantial increases in plasma renin activity.[30,31]

In striking contrast to diazoxide, minoxidil and, to a lesser extent, hydralazine, the calcium-entry blockers do not give rise to sodium retention.[7–9] This may be partly accounted for by the lack of effect on the renin-angiotensin-aldosterone system, but it may also be that they have differing direct effects on the kidney.

Unwanted Effects

The depressant action of verapamil on the cardiac conducting system rarely causes any problem in the treatment of hypertension. Occasionally, the antiarrhythmic properties of the drug may prove an advantage in a patient who has both hypertension and a history of supraventricular tachyarrhythmias.

The major adverse effect reported by patients treated with verapamil is constipation, and this may occasionally necessitate withdrawal of the drug.[32] A small proportion of patients complain of flushing or headache.

Nifedipine appears more likely to provoke symptoms of flushing, headache or burning in the legs; symptoms most often occur a short time after taking the drug and are less of a problem with the sustained release preparation, which causes significantly lower peak concentrations. Nifedipine may infrequently provoke anginal pain at rest in patients with preexisting, but perhaps unrecognized, coronary artery disease.[18,33] The mechanism is uncertain, but the induction of a coronary "steal" phenomenon seems the most likely cause. A not uncommon and occasionally irksome effect of nifedipine is development of ankle edema, which is sometimes quite severe. It typically occurs in the absence of other signs of cardiac failure (1 such patient in our clinic was able to play water polo!) and does not result from primary retention of sodium by the kidney because it is resistant to conventional doses of diuretics.[16] It is widely believed that ankle edema results from a selective dilatation of the precapillary resistance vessels leading to increased capillary pressure, but proof of this hypothesis is lacking.

Neither verapamil nor nifedipine appears to carry the risk of serious immunologic adverse effects such as the drug-induced lupus syndrome that is occasionally seen with hydralazine. Verapamil has no effect on serum lipids.[32]

Clinical Use of Calcium-Entry Blocking Agents in Treatment of Hypertension

Verapamil and nifedipine are both suitable for the initial treatment of patients with mild to moderate hypertension. They offer an alternative to β-adrenoceptor antagonists for patients in whom that group of drugs is contraindicated by coexisting asthma or peripheral vascular disease. A calcium-entry blocker can also be considered for patients in whom a thiazide diuretic might normally be used but is contraindicated by a predisposition to diabetes mellitus, gout or hypokalemia. In theory, verapamil is preferable to nifedipine for use as a sole drug in view of its tendency to slow rather than speed the heart rate; in practice, there seems to be little difference between the 2 agents. It is not yet clear which groups of patients can be expected to respond best to a calcium-entry blocker, but it has been suggested that, in contrast to β-adrenoceptor blockers, it generally is the patients who are older or have suppression of plasma renin activity who have the greatest decrease in pressure.[34] Both verapamil and nifedipine must be given at least twice daily in contrast to the once daily therapy that is available with both β blockers and diuretics. This is a disadvantage.

If a second drug needs to be added to the calcium-entry blocker, it will normally be a diuretic if verapamil has been used. The extent to which the hypotensive actions of the 2 classes of drugs are additive has, however, not yet been defined. If nifedipine has been used initially, it appears logical to add a β blocker as the next step because the effectiveness of this combination is well documented. It is worth noting that nifedipine can often be successfully substituted for the diuretic in patients whose condition was previously controlled by a β-blocker/thiazide combination and in whom withdrawal of the thiazide is necessitated by adverse metabolic effects.

The major established indication for the use of nifedipine is as a third step agent in combination with a β blocker (or α methyldopa) and a diuretic. Nifedipine is clearly preferred to hydralazine in this situation. It is at least as effective in decreasing arterial pressure, probably has a lower incidence of subjective adverse

effects and, most importantly, does not carry the risk of provoking drug-induced lupus syndrome. With the increased use of hydralazine over the past 5 to 10 years, it has become clear that avoidance of this serious immunologic reaction cannot be ensured by restricting dosage to an upper limit of 200 mg/day, and contrary to previous opinion, the kidneys do not always escape involvement.[35] I have successfully substituted nifedipine for hydralazine in several patients in whom the lupus syndrome prohibited continued treatment with the latter drug.

When good control of arterial pressure is achieved with the combination of a β blocker, diuretic and nifedipine, the diuretic can frequently be discontinued without more than a small increase in pressure. This emphasizes what may be the most important distinction between the calcium-entry blockers and other arteriolar dilators. Diazoxide and minoxidil cause such severe sodium retention that it is usually necessary to give high doses of loop diuretics concurrently; hydralazine causes less sodium retention, but it is, nevertheless, usually deemed necessary to give a diuretic with it. Verapamil and nifedipine do not normally cause sodium retention and, although diuretics may sometimes exert a useful additional hypotensive effect, their use is not mandatory.

The response to the first dose of a calcium-entry blocker is not always maintained with subsequent doses. One patient studied in this department had a decrease in pressure from 210/110 to 130/80 mm Hg after a single dose of 20 mg of nifedipine; however, during subsequent short-term treatment with 3 times daily dosage, the drug had little hypotensive effect. The emergence of tolerance does not, however, seem to be a problem during long-term therapy. In those patients who took part in our initial assessment of nifedipine, the response achieved after the first week or so of treatment has been maintained for periods in excess of 5 years.

The use of nifedipine in combination with captopril is currently being evaluated and it appears that it may have a useful role in resistant hypertension when given in this way. It certainly appears eminently sensible to combine inhibition of the potent extrinsic constrictor action of the renin-angiotensin system with inhibition of the intrinsic arteriolar tone.

Limited information is available concerning the antihypertensive effectiveness of calcium-entry blocking agents other than verapamil and nifedipine. Diltiazem, which resembles verapamil in its pattern of action, has been shown to decrease arterial pressure when given in short-[36] and long-term therapy.[37] Several dihydropyridines (the group to which nifedipine belongs) are being evaluated and it is to be hoped that new agents will be found that combine the therapeutic effectiveness of nifedipine with a longer duration of action and a lower incidence of subjective adverse effects.

In summary, the effectiveness of the calcium-entry blocking agents in the treatment of hypertension is now clearly documented; they may be used either alone or in combination with other hypotensive agents. They have advantages in some circumstances over such existing antihypertensives as β blockers and diuretics; they also offer advantages over other currently available dilators because they are free from the more serious adverse effects of the latter drugs. Nifedipine and, to a lesser extent, verapamil produce a significant incidence of subjective adverse effects, but after wide clinical use in patients with angina extending over many years, neither drug is known to cause hazardous adverse effects during long-term treatment. Further experience is required to evaluate the advantages and disadvantages of the calcium-entry blockers and to determine the extent to which they may usefully replace existing drugs in the treatment of hypertension.

Effects of Calcium-Channel Blockers on Myocardial Preservation During Experimental Acute Myocardial Infarction

KEITH A. REIMER, MD, PhD, and ROBERT B. JENNINGS, MD

Calcium antagonists have become accepted agents for the attenuation of myocardial ischemia when it becomes manifest as angina pectoris. However, it is not known whether these agents can protect ischemic myocardium during the early evolution of an acute myocardial infarct. Calcium antagonists could potentially improve myocardial perfusion, by relieving coronary spasm or improving collateral blood flow, and reduce the energy demands of the ischemic myocardium either directly or by reducing heart rate or contractility. In some studies, calcium antagonists have decreased the rate of adenosine triphosphate depletion in ischemia and reduced functional or structural indexes of ischemic injury after relatively brief periods (up to 2 hours) of injury. We have assessed the ability of verapamil to protect severely ischemic myocardium in dogs with a 40-minute test period of circumflex occlusion followed by reperfusion. After 4 days of recovery, infarcts were sized by histologic methods. Untreated dogs had subendocardial infarcts (the more moderately ischemic subepicardial region being salvaged by reperfusion). Pretreatment with verapamil reduced the size of these subendocardial infarcts from 34 ± 8 to 8 ± 3% of the ischemic circumflex vascular bed (anatomic area at risk). Thus, verapamil prevented cell death in a substantial proportion of the severely ischemic subendocardial region that otherwise would have died as a result of the 40-minute test period of ischemia. To establish whether verapamil could prevent cell death for a longer period of time in the less severely ischemic subepicardial region, a 3-hour period of coronary occlusion with reperfusion was studied. This period of occlusion caused infarcts averaging 60 ± 6% of the ischemic area at risk in untreated dogs. Dogs treated with verapamil 15 minutes after occlusion and throughout the remaining 165 minutes of the 3-hour test period had no limitation of infarct size (53 ± 3% of the area at risk). In untreated dogs, infarct size was related inversely to baseline subepicardial collateral flow. Verapamil neither improved collateral flow nor altered the regression of infarct size versus blood flow. Thus, the early protective effect of pretreatment with verapamil was not sustained when ischemia was prolonged to 3 hours and when verapamil was given 15 minutes after the onset of ischemia. In experimental studies from other laboratories, calcium antagonists have had either a protective effect or no effect when infarct size was evaluated after ≥3 hours of coronary occlusion. Preliminary results of clinical trials with calcium antagonists in acute myocardial infarction have not been encouraging. The available experimental data indicate that calcium antagonists can prevent ischemic cell death during relatively brief periods of ischemia if reperfusion is established, but it is uncertain whether these agents can limit infarct size when ischemia is maintained for longer periods.

(Am J Cardiol 1985;55:107B–115B)

The use of calcium antagonists for the attenuation of myocardial ischemia when it manifests as angina is widely accepted. There are many reports supporting the idea that calcium antagonists can delay the detrimental consequences of acute myocardial ischemia. However, it is not clear whether therapy with calcium antagonists can limit ultimate infarct size.

There are a number of hypothetical reasons why calcium antagonists might be beneficial to acutely ischemic myocardium. In the small subset of patients with infarction initiated by vasospasm,[1–3] relief of vasospasm by calcium antagonists could halt the evolution of an infarct.[4–6] A second reason for interest in calcium antagonists is the possibility of improved coronary collateral blood flow based on the known coronary vasodilating properties of those agents.[7] Third, peripheral vasodilation and decreased contractility reduce

myocardial metabolic demands. Fourth, it has been hypothesized that calcium overload may be instrumental in causing ischemic cell death[8] and calcium-entry blockers might delay or prevent this specific mechanism of cellular injury.

Early interest in the use of calcium antagonists in patients with myocardial infarction was stimulated by the observation that reperfusion of acutely ischemic myocardium was followed by so-called explosive cell swelling,[9] massive calcium overload with formation of myofibrillar contraction bands and myofibrillar disruption,[10] as well as by massive mitochondrial loading of calcium (Ca^{++}) with deposition of calcium phosphate densities[11] and consequent abolition of high energy phosphate production (Fig. 1). However, ultrastructural and tracer permeability studies suggest that the massive calcium overload in the setting of reperfusion occurs because of structural disruption of the plasmalemma of the myocyte[12–14] and is not primarily dependent on calcium specific channels (Fig. 2).

Nevertheless, as schematically illustrated in Figure 3, more subtle defects in calcium homeostasis may be detrimental early in the ischemic process, either by accelerating cellular utilization of adenosine triphos-

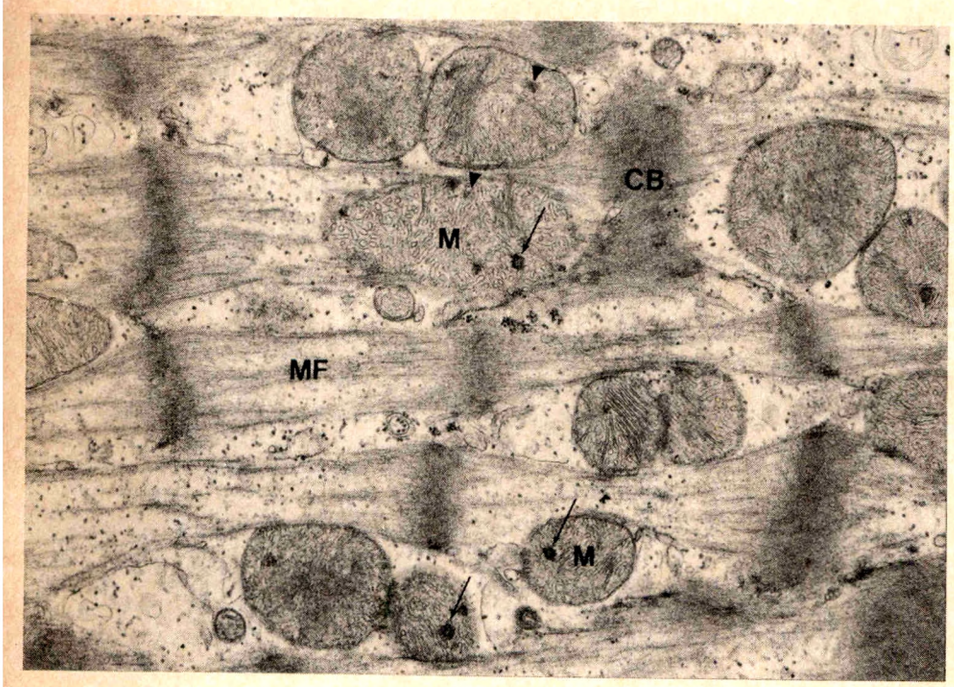

FIGURE 1. Ultrastructural features of contraction band necrosis in cardiac myocyte from subendocardial zone of ischemic region of dog heart after 40 minutes of coronary occlusion and 10 minutes of reperfusion. Myofibrils (MF) have been completely disrupted with myofibrillar proteins from several adjacent sarcomeres condensed into tangled masses referred to as contraction bands (CB). There has been massive influx of calcium into myocyte as evidenced by annular crystalline mitochondrial (M) densities (**arrows**) that have been shown to contain calcium and phosphate.[10,11] These changes, referred to as contraction band necrosis, are characteristic of myocardial cell death associated with ischemia and reperfusion. **Arrowheads** indicate amorphous matrix densities that are also characteristic of irreversible ischemic cell injury and can be seen before and after reperfusion.[12] Illustration from the work of Rocco et al.[83] Magnification × 22,000, reduced 29%.

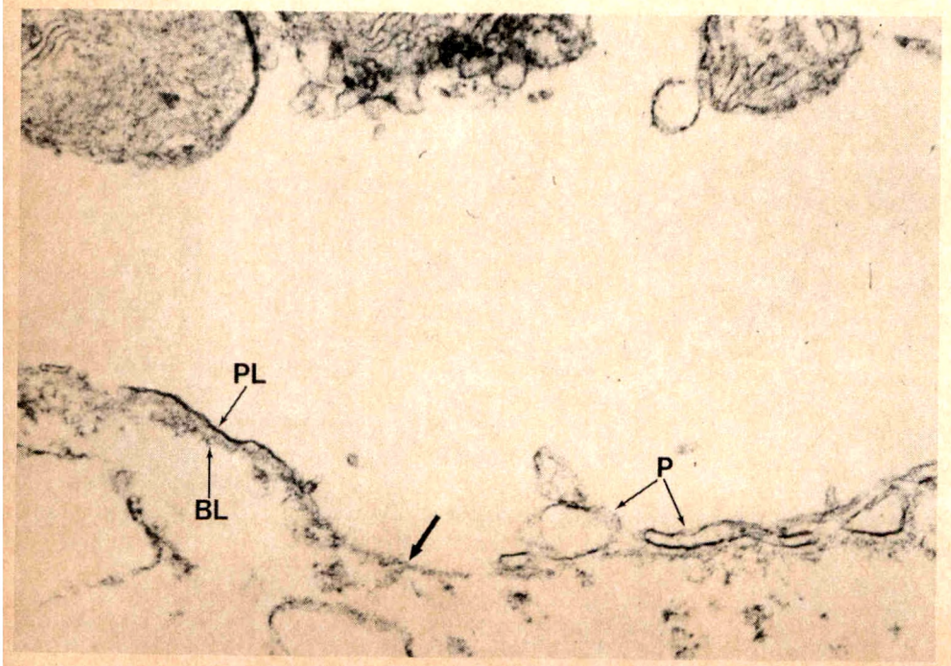

FIGURE 2. Sarcolemmal disruption observed in myocyte from subendocardial zone of ischemic region of dog heart after 40 minutes of coronary occlusion and 5 minutes of reperfusion. There is large edematous space (**central clear area**) separating sarcolemma from myofibrillar apparatus of myocyte. Sarcolemma is composed of basal lamina (BL) or glycocalyx and trilaminar unit membrane, plasmalemma (PL). Basal lamina appears intact but plasmalemma has been disrupted in some areas (for example **large arrow**) and has reformed as circular profiles (P) in other areas. Osmium tetroxide fixation; magnification × 69,000, reduced 28%. Reproduced with permission from *Am J Pathol.*[12]

phate (ATP) or by activating catabolic enzymes such as phospholipases, both of which might speed the onset of lethal cellular injury.[13] Thus, there are a number of reasons to speculate that calcium antagonists might protect ischemic myocardium.

The hypothesis that calcium antagonists protect ischemic myocardium has been tested in a large number of laboratories, using a variety of experimental models and different endpoints. We will review briefly some of the evidence accumulated in published reports, beginning with some of the more indirect experimental endpoints and following with direct studies of the effects of calcium antagonists on myocardial cellular injury and infarct size.

Studies in the mid- and late 1970s showed that calcium antagonists generally improved electrocardiographic indexes of injury in models of regional ischemia.[15–18] However, electrocardiographic improvement with nifedipine was dependent on dose,[18] and no electrocardiographic improvement was observed in cats with coronary occlusion treated with verapamil.[17]

Calcium antagonists have had variable but generally positive effects on contractile function of ischemic segments during acute coronary occlusion[19–22] and have improved postischemic recovery of function in models of global or regional ischemia followed by restoration of coronary perfusion.[23–37] The latter results have been of particular interest with respect to the possible use of calcium antagonists as cardioplegic agents during cardiac surgery.

More direct indexes of cell damage such as mitochondrial function,[37–41] myocardial calcium accumulation[42] or enzyme release,[18,25,43–46] gross or histologic myocardial necrosis[47–49] and ultrastructural changes[32–38] also have been studied in various models of global or regional ischemia or hypoxic perfusion. These studies have all involved relatively brief periods of injury, that is, ≤2 hours under normothermic conditions. Most of these published reports have shown that calcium-channel blockade, either with verapamil, nifedipine or diltiazem, reduced the deleterious effect of ischemia over the time period studied.

If calcium antagonists can delay the cellular consequences of ischemia and can protect ischemic myocardium for relatively brief periods of time, can they also limit infarct size when ischemia is more prolonged? Several laboratories have published results of therapy with calcium antagonists in experimental animals, during longer periods of ischemia.

Karlsberg et al[50] evaluated verapamil therapy begun 5 hours after coronary occlusion in an awake dog model. Verapamil failed to limit infarct size, as measured by myocardial creatine kinase (CK) depletion 24 hours after coronary occlusion. However, in dogs with acute coronary occlusions, most of the myocardium that will undergo infarction has already died by 3 hours[51,52] and it is likely that little potentially salvageable ischemic myocardium remained at the time therapy was started in their study.

At least 5 studies have shown limitation of experimental infarct size with calcium antagonists, when measured at times ranging from 6 hours to 2 days after coronary occlusion. Henry et al[53] showed less CK loss from 24-hour-old infarcts that had been induced by coronary occlusion in awake dogs and treated with nifedipine beginning 30 minutes after coronary occlusion. DeBoer et al[54] observed smaller infarcts, as estimated grossly, 8 hours after occlusion, using triphenyl tetrazolium chloride (TTC) staining in anesthesized dogs in which verapamil therapy was started 1 hour after occlusion. Zamanis et al[55] showed a reduction in histologic infarct size in rats with 48-hour coronary occlusions treated with diltiazem. Alps et al[56] achieved marked limitation of infarct size with a newer calcium antagonist, nicardipine, in baboons. In this study, infarct size was assessed grossly based on para-nitroblue tetrazolium staining 6 hours after coronary occlusion. Infarct size was normalized for the area at risk, which was assessed from x-rays of ventricular slices after postmortem injection of the coronary arteries with contrast material. Most dramatically, Yellon et al[57] have observed marked limitation of infarct size, measured grossly, based on TTC staining 24 hours after coronary occlusion in dogs treated with verapamil.

In contrast, Alps et al[56] showed no effects of verapamil or nifedipine on infarct size when evaluated using the same protocol used to study nicardipine. Also, Geary et al[58] showed no effect of nifedipine in baboons when infarcts were caused by 2 hours of coronary occlusion followed by reperfusion.

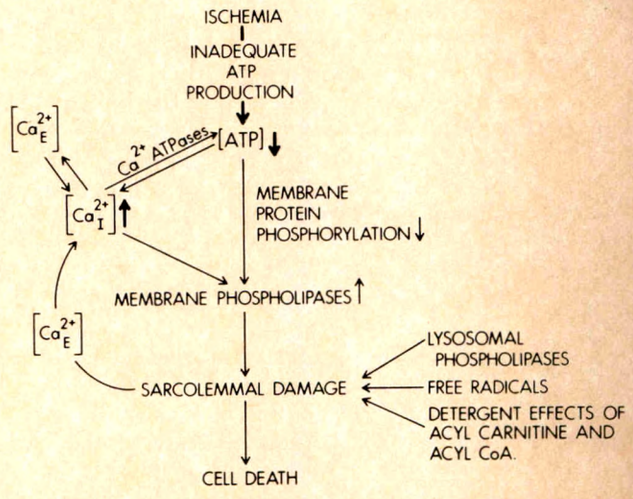

FIGURE 3. Potential relations between adenosine triphosphate (ATP) depletion, calcium influx and sarcolemmal damage, which forms basis for various hypotheses of events leading to sarcolemmal damage. ATP of ischemic myocytes decreases because ATP utilization exceeds capacity of anaerobic glycolysis to produce high energy phosphates. Intracellular calcium (Ca_I^{2+}) may increase either because of increased membrane permeability to calcium or because of inadequate ATP to support mechanisms responsible for calcium extrusion from cell or sequestration of calcium by sarcoplasmic reticulum. Increased Ca_I^{2+} also may accelerate ATP depletion through calcium-activated ATPases. Sarcolemmal damage occurs at ATP levels of 3 to 8% of control. Mechanism of damage is unknown. One explanation is activation of endogenous sarcolemmal phospholipases by increased Ca_I^{2+} or depressed phosphorylation of membrane proteins that ordinarily inhibit activity of endogenous phospholipases of sarcolemma. Lysosomal phospholipase release, free radicals or detergent action of acyl carnitine or acyl coenzyme A (CoA) are also possible causes of sarcolemmal damage in myocardial ischemia. I = inner (subendocardial); LAD = left anterior descending nonischemic arterial region; M = middle, O = outer (subepicardial) zones of the ischemic region.

We have used 2 models for testing the effects of an intervention on myocardial ischemic injury and infarct size.[47,59–63] These models use anesthetized open-chest dogs with temporary occlusions of the circumflex artery. In this species, ischemic myocardium does not all undergo infarction simultaneously but there is a transmural progression of injury (Fig. 4).[63] By 40 minutes, the most severely ischemic subendocardial region is irreversibly injured but the more moderately ischemic subepicardial region is still viable. By 3 hours, much of this moderately ischemic zone also is irreversibly injured and reperfusion at this time results in infarcts only slightly smaller than infarcts caused by permanent coronary occlusion.[63]

In one model, we tested the effect of interventions on the amount of necrosis induced by a 40-minute test period of ischemia. In this test system, moderately ischemic subepicardial myocardium is spared by reperfusion,[63] irrespective of treatment; the question is whether therapy can delay injury in severely ischemic myocardium for the 40-minute duration and thereby prevent or reduce the size of subendocardial infarcts. In the other model, therapy was given during 3 hours of ischemic injury. Although the subendocardial region would probably be beyond salvage in this test system, we wanted to determine whether cell injury could be delayed in the moderately ischemic subepicardial myocardium.[61–63] We also wanted to see if the transmural extent of these infarcts could be limited. We tested verapamil in both models.[62]

In the 40-minute test system, we administered verapamil before coronary occlusion. After 40 minutes of ischemia, reperfusion was established. The primary endpoint was infarct size, measured histologically 4 days after the acute event. The secondary endpoints measured were the baseline variables that influence infarct size: collateral blood flow, which was measured with tracer microspheres, anatomic size of the occluded vascular bed, which was measured by postmortem coronary dye injections, and hemodynamic parameters which influence myocardial metabolic requirements. Heart rate, mean blood pressure and left ventricular (LV) systolic pressure all were reduced in the verapamil-treated group but LV end-diastolic pressure was unchanged (Table I). Compared with blood flow before drug administration, verapamil caused a 50% increase

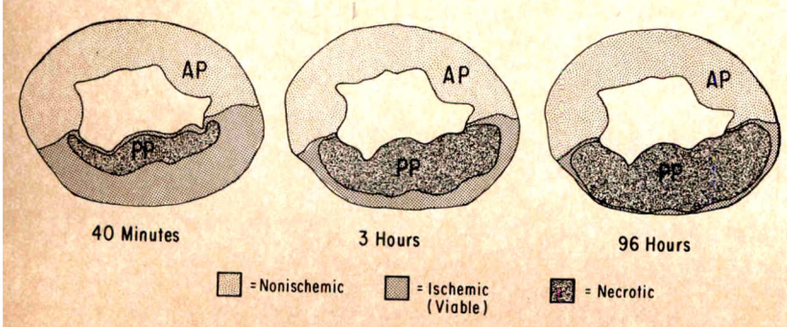

FIGURE 4. Progression of cell death versus time after left circumflex coronary artery occlusion. Necrosis occurs first in subendocardial myocardium. With longer occlusion, wavefront of cell death moves from subendocardial zone across wall to involve progressively more of transmural thickness of ischemic zone. In contrast, lateral margins in subendocardial region of infarct are established as early as 40 minutes after occlusion and are sharply defined by anatomic boundaries of the ischemic bed. AP = anterior papillary muscle; PP = posterior papillary muscle. Reproduced with permission from *Lab Invest.*[63]

in myocardial blood flow in nonischemic myocardium. Collateral blood flow averaged 5, 11 and 22% of control in the subendocardial, mid- and subepicardial regions of ischemia in control animals and was slightly less in dogs given verapamil (Table II).

Forty minutes of ischemia in untreated dogs caused subendocardial infarcts that averaged 13% of the left ventricle and 34% of the occluded circumflex vascular bed (Table III). Despite the somewhat worse myocardial perfusion during ischemia, verapamil markedly reduced necrosis to 3% of the left ventricle and 8% of the ischemic vascular bed. Thus, in this particular experimental model, verapamil had a dramatically positive effect on ischemic myocardium, and clearly delayed the onset of cell death. These results are consistent with results of the several other studies showing protective effects of calcium antagonists during relatively brief periods (≤2 hours) of myocardial ischemia or hypoxia.

The mechanism for early protection by calcium antagonists is not established. One possibility is improved collateral blood flow. However, verapamil did not improve collateral flow in our experiments. Also, in models of global ischemia in which there is no collateral flow, improved collateral blood flow clearly is not involved in the cardioprotective effects. In other studies of regional ischemia, the effects of calcium-channel blockade on coronary collateral flow have been variable. Several laboratories in addition to our own have observed no improvement in collateral flow with various calcium antagonists in dogs with complete coronary occlusion.[22,50,64–67] Other studies have observed improved blood flow in samples with initially moderately reduced flow.[53,68–70] However, these results showing improved collateral flow can most likely be explained by the failure to identify the interface between ischemic and nonischemic regions, with consequent inclusion of nonischemic myocardium in some ischemic samples.

It seems more likely that the protective effects of calcium antagonists are due to direct cellular actions. In this regard, it has been demonstrated in several studies that calcium antagonists do reduce the rate of high energy phosphate depletion during ischemic or hypoxic injury.[24,38,40,71,72] Figure 5 nicely illustrates 2 hypotheses regarding possible mechanisms of protection.[40] Inhibition of calcium influx may result either directly or indirectly in a reduction of myocardial ATP utilization. This may be beneficial either by better maintenance of calcium homeostasis and prevention of calcium overload, or through maintenance of other ATP dependent processes, the absence of which could be lethal. Previous studies have shown a close relation between marked depletion of ATP and the adenine nucleotide pool and the onset of lethal myocardial ischemic cell injury.[13,73]

We used a 3-hour period of ischemia to evaluate whether verapamil can prevent infarction in areas of myocardium that are more moderately ischemic.[62] By 3 hours, most of the myocardium that would become infarcted with a permanent coronary ligation is already dead and reperfusion at this time achieves at best only about a 10% limitation in infarct size.[63] If therapy during a 3-hour occlusion is successful, it will limit a potentially transmural infarct to one which is subendocardial.[61,63] Drug therapy or saline (control) was begun 15 minutes after coronary occlusion and continued through the 3-hour test period of ischemia. After 3 hours, reperfusion was established and the dogs were allowed to live 4 days. As with the 40-minute model described previously, the major endpoint was infarct size, quantitated from histologic sections. Again, baseline variables that influence infarct size—size of the ischemic vascular bed, collateral blood flow and hemodynamic parameters—were measured.

TABLE III Area at Risk and Infarct Size in Control- and Verapamil-Treated Dogs with 40 Minutes of Ischemia and 4 Days of Reperfusion

	Dogs (n)	Size of LCC Bed	Necrosis % of LV	Necrosis % of LCC Bed
Control	6	39.9 ± 1.8	13.0 ± 2.8	34.3 ± 8.0
Verapamil	8	38.6 ± 2.1	3.1 ± 1.6*	8.1 ± 2.9*

Values are means ± standard error of the mean.
* $p < 0.01$.
LCC bed = occluded circumflex coronary region at risk of infarction; LV = left ventricle.

In this study, heart rate and blood pressure were both reduced somewhat by verapamil but cardiac output was maintained and LV end-diastolic pressure was not different between the verapamil and the control groups (Fig. 6). Verapamil caused a significant increase in blood flow to nonischemic myocardium but did not improve subendocardial or subepicardial collateral blood flow in the ischemic zone.

In comparison to the dramatically positive results with verapamil in the 40-minute model, infarct size was

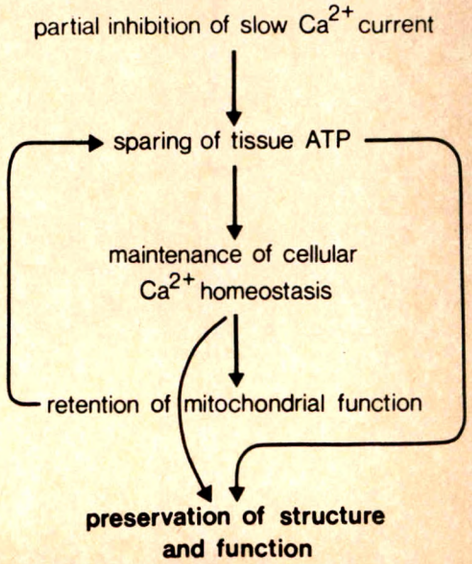

FIGURE 5. Schematic representation of possible pathways involved in protective effect of drugs inhibiting slow channel calcium transport (calcium antagonists). Reproduced with permission from *Am J Cardiol.*[40]

not reduced by verapamil in the 3-hour study (Fig. 7). This negative result was observed when infarct size was expressed as a percentage of the left ventricle or as a percentage of the anatomic area at risk. In addition, the transmural extent of the infarct was not altered.

Because collateral blood flow is such an important determinant of infarct size,[51,63,74] infarct size results should be carefully examined in comparison to this variable. Subendocardial infarctions always develop in untreated dogs, but the subepicardial region may be involved to a variable extent and there is an inverse correlation between the transmural extent of the infarct and collateral blood flow to the subepicardial myocardium.[63] One way to incorporate measurements of collateral blood flow into the analysis of infarct size is illustrated in Figure 8.[61–63] With any therapy that limits infarct size, infarcts must be smaller than predicted from a baseline (pretreatment) measurement of collateral flow. Thus, successful limitation of infarct size would alter the regression of infarct size (as a percentage of area at risk) versus baseline subepicardial collateral flow. In addition, when the regression of infarct size on pre- versus posttreatment measures of infarct size are compared, information can be gained about the mechanism of the protective effect. Drug therapy that limits infarct size must do so either by improving collateral blood flow or by having beneficial effects on metabolism or structural integrity of the ischemic myocyte despite continued ischemia.[75] With therapy that affords metabolic or structural protection without effect on collateral flow, the regression of infarct size versus collateral flow would be displaced downward from the control relation (Fig. 8, left). Conversely, therapy that alters collateral flow would shift points along the curve when a posttreatment measure of flow is used (Fig. 8, right).

The relation between infarct size and flow is illustrated for control infarcts in Figure 9, top, and for verapamil-treated infarcts in Figure 9, bottom.[62] At most, 2 of 11 verapamil-treated infarcts were smaller than expected from baseline measurement of collateral blood flow, and verapamil may have provided protec-

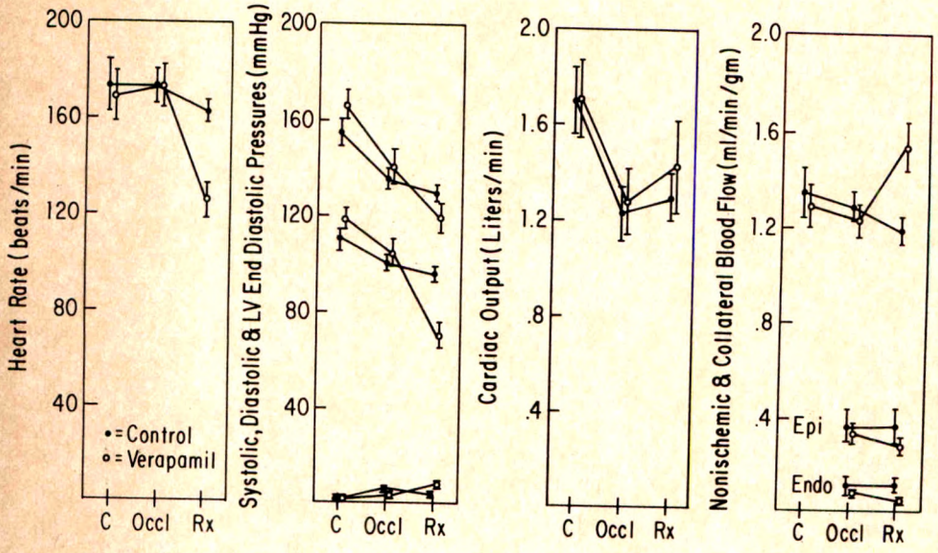

FIGURE 6. Effects of coronary occlusion and verapamil therapy on hemodynamic parameters and regional blood flow. Measurements were made before occlusion (C), after occlusion but before treatment (Occl) and after treatment (Rx). Heart rate and blood pressure both were reduced somewhat by verapamil but cardiac output was maintained and left ventricular end-diastolic pressure was not different between control (**closed circle**) and verapamil-treated (**open circle**) groups. Verapamil caused significant increase in blood flow to nonischemic myocardium but did not improve subendocardial (Endo) or subepicardial (Epi) blood flow in ischemic zone. Reproduced with permission from *Lab Invest.*[62]

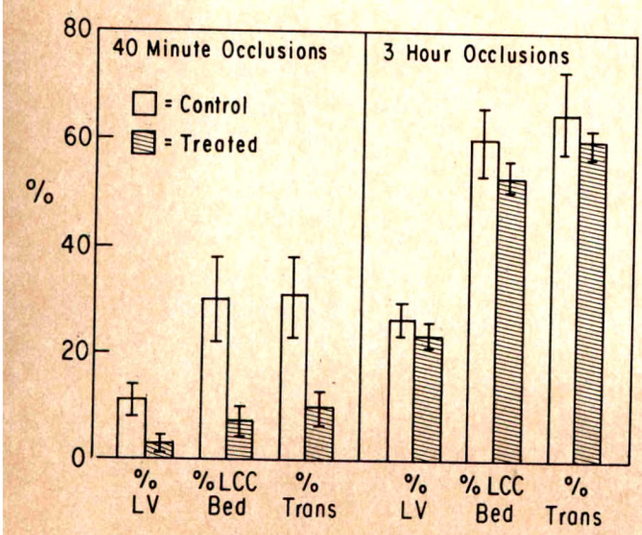

FIGURE 7. Effect of verapamil on myocardial infarct size induced by 40 minutes versus 3 hours of temporary coronary occlusion. Verapamil had dramatically positive effects when tested in 40-minute model (**left**), but in 3-hour study (**right**), infarct size was not reduced by verapamil. Latter negative result was observed when infarct size was expressed as percentage of left ventricular (LV) or as percentage of anatomic area at risk (percent left circumflex coronary [LCC] bed). In addition, transmural (trans) extent (percent transmural) of infarct was not altered. Reproduced with permission from *Lab Invest.*[62]

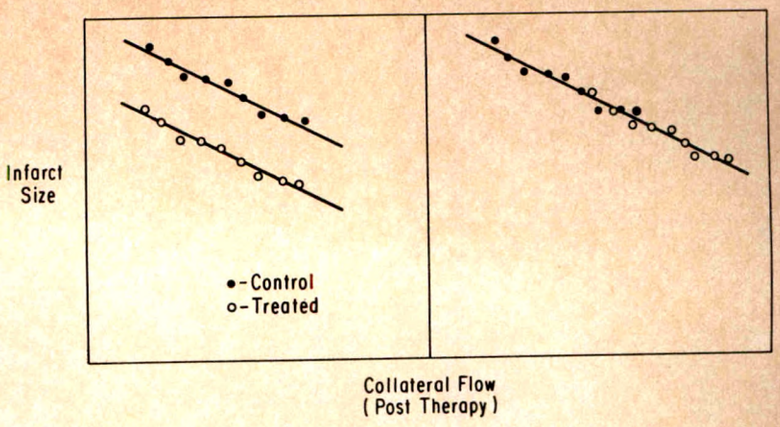

FIGURE 8. Hypothetical results of ideal experiment to illustrate how relation between infarct size and collateral blood flow can be used to evaluate effects of therapy. With any therapy that limits infarct size, infarcts would be smaller than predicted by baseline collateral flow measurement, and regression of infarct size versus flow would shift downward. With intervention that does not alter collateral blood flow, regression line of infarct size versus flow also would shift downward when posttreatment measurements of flow is used (**left**). Conversely, intervention that limits infarct size by improving collateral blood flow would shift points to right along control regression line when posttreatment measurement of flow is used (**right**). Thus, incorporation of collateral flow measurements should permit detection of positive effect with greater precision and provide information about mechanism of treatment effect.

tion. The possibility that metabolic protection was obscured by the slight decrease in collateral blood flow was excluded because the regression using the posttreatment measure of collateral flow (obtained 1 hour after coronary occlusion) was similar to that shown in Figure 9, bottom.

These results have been confirmed in a considerably larger number of dogs as part of a National Institutes of Health collaborative study (the AMPIM study)[76] in which verapamil was simultaneously reevaluated in our laboratory and in the laboratories of Becker at Johns Hopkins and Cobb at the Duke Veterans Administration. The major endpoints were similar in all 3 studies. The Hopkins and Veterans Administration studies differed from ours in that we used a reperfusion model, while they used awake, chronically instrumented dogs with permanent coronary occlusions. All 3 laboratories in this collaborative effort showed no effect of verapamil on infarct size.

Why calcium antagonists show protective effects in some studies but not in others is not known. It is possible that different results may be due to differences among the individual drugs, the dose regimens or the different responses to therapy among different animal models. However, it is clear that in all animal models of myocardial infarction, infarct size is influenced by a number of biologic variables unrelated to therapy per se. All of the studies reporting limitation of infarct size with calcium-antagonist therapy during ≥6 hours of ischemia have failed to consider 1 or more of the important determinants of infarct size, such as the size of the anatomic area at risk or the baseline collateral blood flow measurement.[51,63,74,77,78] Thus, uncontrolled differences among treated and untreated animals may have occurred and caused false-positive results. In addition, we postulate that the markedly positive results in the study of Yellon et al[57] may have been due to the peculiarities of the model used: coronary occlusion was achieved by injecting a small plug into the coronary arteries and the coronary vasodilating action of the verapamil may have caused distal migration of the plug.

Relatively little information is available regarding the effect of calcium antagonists on myocardial infarct size in patients. The results of 2 separate clinical trials using

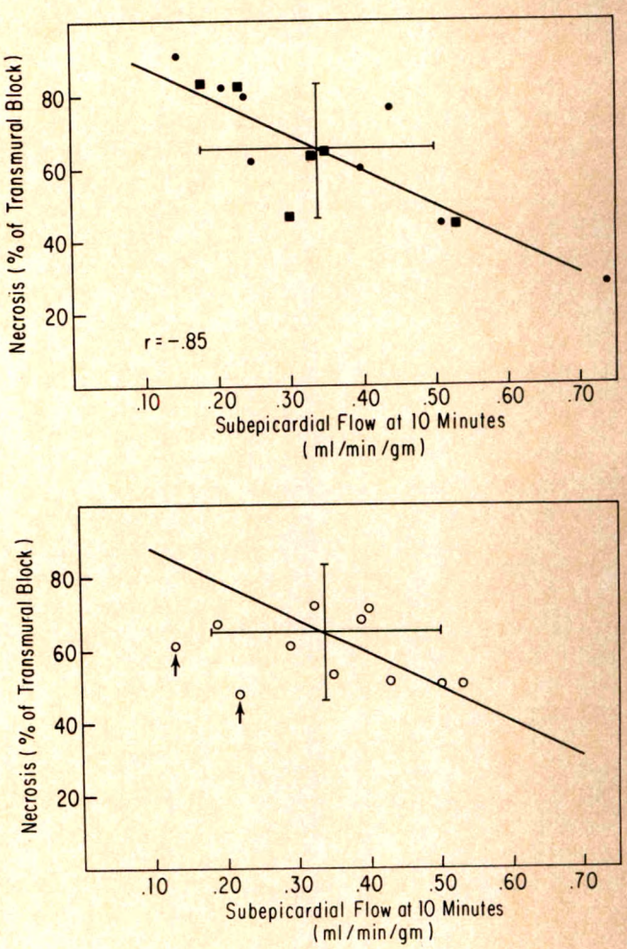

FIGURE 9. Relation between transmural extent of infarction after 3 hours of coronary occlusion and collateral blood flow in subepicardial region is shown for untreated dogs (**top**) and verapamil-treated dogs (**bottom**). In the top panel, **solid circles** represent control dogs from this study and **solid squares** represent dogs studied using identical protocol for another unpublished study. Strong inverse relation ($r = -0.85$) between extent of infarct and intrinsic collateral flow shows that collateral flow is important determinant of infarct size. Bottom panel shows best fit line and standard deviations from control group illustrated in top panel, but control points have been replaced by verapamil points. Even when considered in relation to collateral blood flow, verapamil, with 2 possible exceptions (**arrows**), had no effect on infarct size. This analysis is based on collateral flow measured after coronary occlusion but before administration of verapamil. Reproduced with permission from *Lab Invest.*[62]

nifedipine in patients with acute myocardial infarctions have been reported to date. In the Norwegian trial,[79] infarct size, assessed by plasma CK curves, was similar in both nifedipine-treated and control groups. No protective effect was observed even when analysis was limited to patients who were treated within 3 hours of onset. Muller et al[80] reported that nifedipine did not alter the incidence of myocardial infarction in patients admitted with threatened myocardial infarction nor did it limit CK estimates of infarct size in patients admitted because of either overt or threatened myocardial infarction.

In summary, it is clear from much accumulated evidence that calcium antagonists, including verapamil, delay the early progression of ischemic injury. Calcium-channel blockers delay the depletion of high energy phosphates as well as other metabolic consequences of ischemia. However, the mechanism of the initial prevention of ischemic cell injury is not established. It is possible that inhibition of calcium influx through the calcium channels delays a calcium overload. Most evidence suggests that calcium blockers do not improve collateral blood flow in models of regional ischemia.

Because of early protection, calcium antagonists may be beneficial as adjuncts to cardioplegia during cardiac injury. Extrapolation of experimental results to clinical settings must be done with caution because the pathogenesis of myocardial infarction in man is complex and still not fully understood. Several possible causes of infarction may occur singly or in combination. Many infarcts are the result of acute thrombotic occlusion of previously stenotic vessels.[81,82] Others may be precipitated by spasm,[1,2] by hemodynamic or neurogenic factors or by platelet aggregation[3] superimposed on chronic atherosclerotic disease. In patients with abrupt coronary occlusion and few preformed collateral vessels, myocardial infarction might evolve to rapid completion in a time frame similar to that observed in our studies in dogs. In patients with extensive preformed collateral vessels or with incomplete or intermittent coronary occlusion, infarction might occur more slowly or intermittently.

Many of the experimental models of infarction reviewed here are most analogous to the clinical situation in which abrupt and fixed coronary occlusion occurs in a heart with some but relatively few preformed collateral vessels. Calcium antagonists administered after the onset of ischemia would clearly be most beneficial in those few patients whose infarction was initiated by vasospasm that could be abolished by these drugs. Whether calcium antagonists can delay myocardial cell death in patients with fixed coronary occlusion is uncertain, but it seems likely that such therapy would not prevent myocardial cell death indefinitely in the absence of early reperfusion. Our results suggest that the best chance for limitation of infarct size would occur in those patients who had been treated on a long-term basis with calcium antagonists and in whom either spontaneously or therapeutically induced reperfusion occurred relatively early after the onset of acute coronary occlusion.

Calcium Antagonists for Acute Ischemic Heart Disease

MICHAEL D. WINNIFORD, MD, JAMES T. WILLERSON, MD, and L. DAVID HILLIS, MD

The pharmacologic and physiologic effects of the slow-channel calcium antagonists verapamil, nifedipine and diltiazem are reviewed. Relevant pathophysiologic features of various acute ischemic heart disease syndromes are also reviewed and the clinical applications of the slow-channel calcium antagonists to acute ischemic heart disease syndromes in patients are discussed.

(Am J Cardiol 1985;55:116B–124B)

The slow-channel calcium antagonists verapamil, nifedipine and diltiazem dilate coronary arteries and increase coronary blood flow but exert varying effects on heart rate, atrioventricular (AV) nodal conduction and myocardial contractility.[1–3] The purpose of this review is 2-fold: to describe the pharmacologic and physiologic effects of these agents, and to identify their role in the treatment of patients with acute ischemic heart disease, including Prinzmetal's, or variant, angina pectoris, unstable angina pectoris and acute myocardial infarction.

Physiologic Considerations

Calcium ions play a central role in modulating myocardial contractility and vascular smooth muscle tone (Fig. 1 and 2). In cardiac myocytes, the action potential initiates a slow inward movement of calcium through specialized sarcolemmal channels (so-called slow calcium channels), and this calcium current is responsible for the plateau phase of the action potential. In turn, the small amount of calcium entering the myocyte through the slow calcium channels (and by other mechanisms) causes the release of larger amounts of calcium from intracellular storage sites, primarily the sarcoplasmic reticulum (Fig 1).[4] The calcium that is released from intracellular storage sites is bound to the regulatory protein troponin, leading to the interaction of actin-myosin and resultant sarcomere shortening. Pharmacologic antagonism of the slow calcium channels interferes with excitation-contraction coupling, thus diminishing myocardial contractility.

From the Department of Internal Medicine (Cardiology Division) at the University of Texas Health Science Center at Dallas, Southwestern Medical School, Dallas, Texas. This study was supported in part by Ischemic SCOR Grant HL-17669 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, and by the Moss Heart Fund, Dallas, Texas.

In vascular smooth muscle, changes in vascular tone depend on the movement of calcium from the extracellular to the intracellular space (Fig. 2),[5,6] where it is bound to the regulatory protein calmodulin.[7,8] The calcium-calmodulin complex activates myosin light chain kinase, resulting in smooth muscle contraction. A decrease in transsarcolemmal calcium entry reduces smooth muscle tone and causes vasodilation. The mechanism by which the slow-channel calcium antagonists inhibit transsarcolemmal calcium influx is unknown. Binding studies with both the dihydropyridine (nitrendipine and nifedipine) and nondihydropyridine calcium antagonists (verapamil and diltiazem) have indicated different myocardial sarcolemmal binding sites or different affinities for binding or both.[9,10]

Pathophysiologic Features of Acute Ischemic Heart Disease Syndromes

Prinzmetal's (variant) angina pectoris is characterized by angina at rest, ST-segment elevation during chest pain, spasm with focal obliteration of the lumen of a large or medium-sized coronary artery and alleviation of chest pain and ST-segment elevation as the spasm resolves (Fig. 3).[11,12] This entity should be suspected in the patient who has angina primarily at rest and the diagnosis should be confirmed by obtaining an electrocardiogram during chest pain.[13] Additional clinical features may include episodic variations in anginal activity, angina with exercise and the occurrence of coronary arterial spasm in a small coronary artery, resulting in ST-segment depression and T-wave inversion. Ergonovine maleate provokes coronary arterial spasm during periods of anginal activity in susceptible persons.[14,15]

The causes of coronary arterial spasm are unknown, but several have been suggested, including increases in the local concentration of thromboxane A_2,[16] vasopressin[17] or histamine[18]; damage to the coronary endothelium and subsequent vasoconstrictor responses to a variety of agonists[19–21]; and diminished production

or sensitivity to the vasodilator prostaglandin prostacyclin. About 20% of patients with Prinzmetal's angina have angiographically normal or minimally diseased coronary arteries, whereas the remainder have significant coronary arterial stenoses; therefore, some patients may have 2 mechanisms responsible for angina: a decrease in myocardial oxygen delivery (caused by coronary spasm) and a relative increase in myocardial oxygen demand associated, for example, with stress and exercise.

Unstable angina pectoris is characterized by increasingly frequent episodes of angina with lesser degrees of effort; in most patients, angina also occurs at rest.[22,23] Most of these patients have physiologically significant coronary arterial stenoses, although the extent of coronary disease varies widely.[24] The major pathophysiologic mechanism responsible for this syndrome is a decrease in myocardial oxygen delivery,[25] which may be caused by coronary arterial spasm,[25] platelet aggregation at sites of critically narrowed coronary arteries (Fig. 4 and 5),[16,26,27] or a progressive decrease in coronary arterial luminal diameter. Thus, it should be possible for several different causes of abrupt and progressive alterations in coronary arterial luminal diameter to lead to angina pectoris at decreasing levels of effort or rest or both. Theoretically, pharmacologic interventions that improve coronary blood flow through such stenotic arteries should help alleviate this clinical problem. Such interventions might include nitrates, selected calcium antagonists, agents that interfere with platelet aggregation, coronary arterial revascularization, or some combination of these.

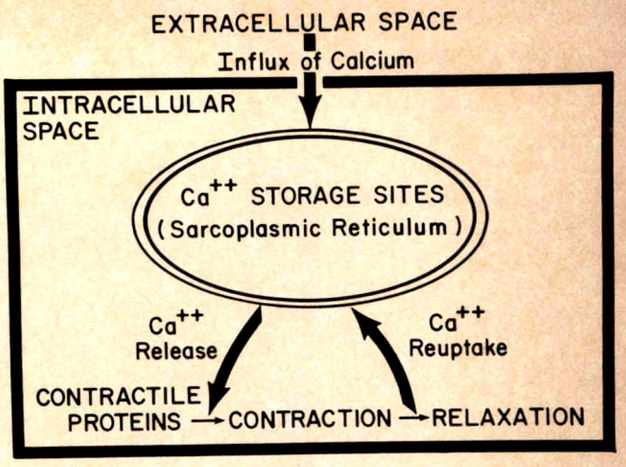

FIGURE 1. Schematic representation of role of calcium (Ca^{++}) in regulating myocardial contractility and vascular smooth muscle tone. After entering the cell, calcium is stored in the sarcoplasmic reticulum, from which it is periodically released and binds to contractile proteins, leading to contraction. Influx of calcium into the cell and its subsequent release from sarcoplasmic reticulum occur through slow channels and, therefore, are inhibited by the slow-channel calcium antagonists. Reproduced with permission from *Angiology*.[1]

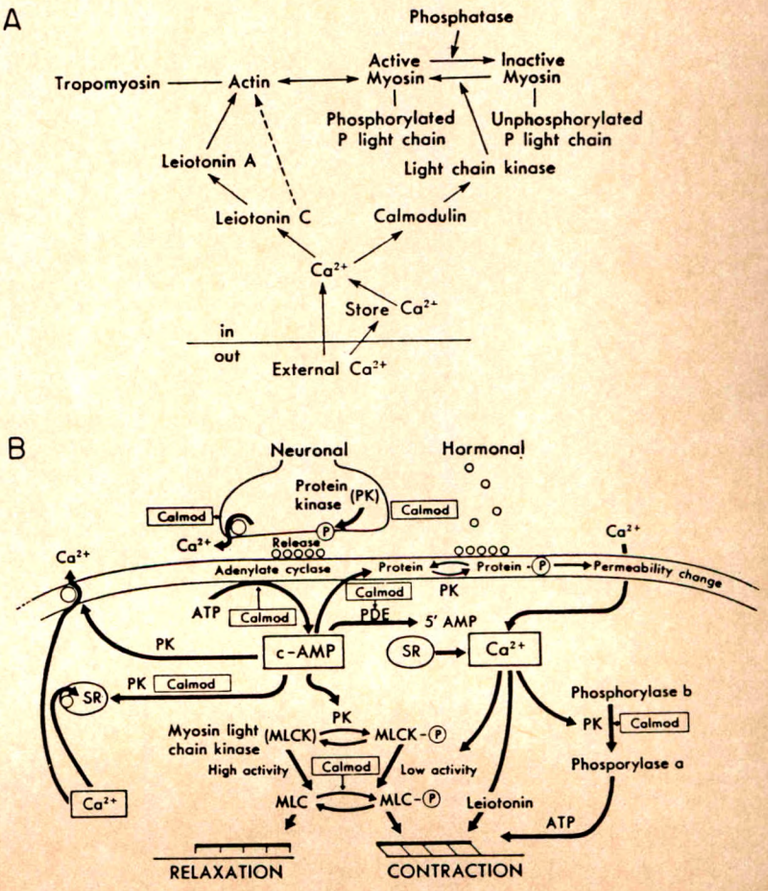

FIGURE 2. Calcium's role in regulating myocardial contractility and vascular smooth muscle tone. Two different concepts for calcium (Ca^{2+}) regulation, leiotonin C (**A**) and calmodulin (**B**), are shown. **Solid arrows** indicate direction of binding, interaction and activations. **A, dashed arrow** suggests possibility of binding protein (17-k dalton acidic protein) that is distinct from calmodulin. Ca^{2+} initiates the actin-myosin interaction by binding to leiotonin C, which itself interacts with leiotonin A (85-k dalton substance, actin-binding protein) and tropomyosin, causing actin-activation of myosin ATPase activity. Other hypothesis (**B**) ("calmodulin hypothesis") suggests that Ca^{2+} triggers actin-myosin interaction by binding to calmodulin, which then activates the kinase catalyzing phosphorylation of myosin, required for actin activation. Reproduced with permission from *Am J Physiol* 1982;243:H653. ATP = adenosine triphosphate.

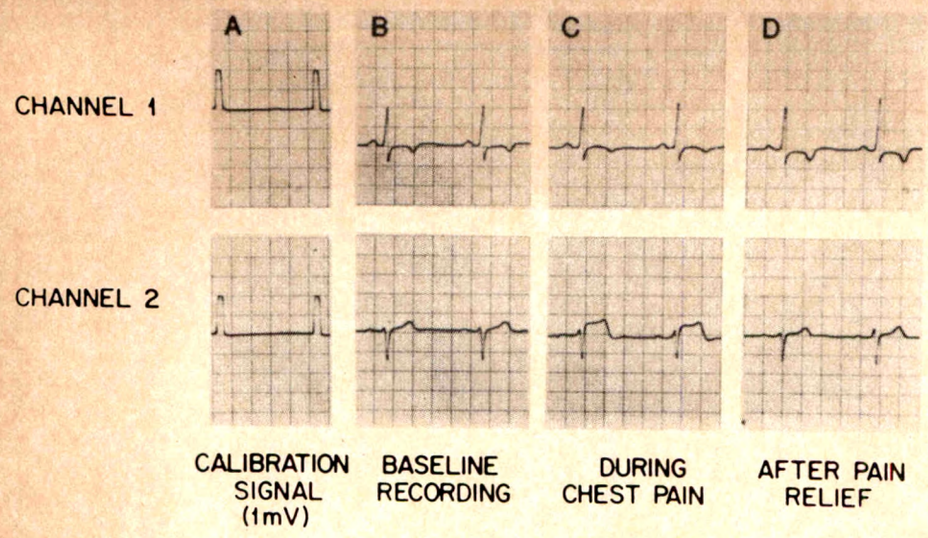

FIGURE 3. Calibrated Holter monitor recordings in patient with Prinzmetal's (variant) angina pectoris. At baseline, ST segments appear normal. During chest pain, ST-segment elevation of 2 to 3 mm occurs in channel 2. After pain relief, ST segments return to baseline, and there is no evidence of infarction (no Q waves or loss of R-wave voltage). Reproduced with permission from Willerson JT, Hillis LD, Buja LM. *Ischemic Heart Disease: Clinical and Pathophysiological Aspects.* New York: Raven Press, 1982:85.

Acute myocardial infarction that is transmural is usually caused by coronary arterial thrombosis, often occurring as a consequence of hemorrhage into an atherosclerotic plaque.[28,29] However, postmortem examinations have suggested that coronary arterial thrombosis occurs in only approximately 30% of patients with acute subendocardial infarcts.[28] Instead, acute subendocardial infarction may be caused by a profound increase in myocardial oxygen demand in a patient with severe coronary arterial stenoses or a prolonged decrease in myocardial oxygen delivery or both, such as might occur with coronary arterial spasm, platelet aggregation at the site of a severely narrowed coronary artery, hemorrhage into an atherosclerotic plaque with subsequent thrombosis, progressive coronary arterial luminal diameter narrowing, or some combination of these.[28]

Pharmacologic Considerations

Because the slow-channel calcium antagonists cause peripheral and coronary vasodilation,[2] they may decrease systemic arterial pressure, afterload and myocardial oxygen demand. In response to this, a reflex increase in coronary vascular resistance may occur, resulting in increase, decrease or no change in coronary blood flow. In isolated cardiac muscle, each of these agents depresses contractility in a dose-dependent manner,[30] but the magnitude of this decrease in patients depends on the slow-channel calcium antagonist used

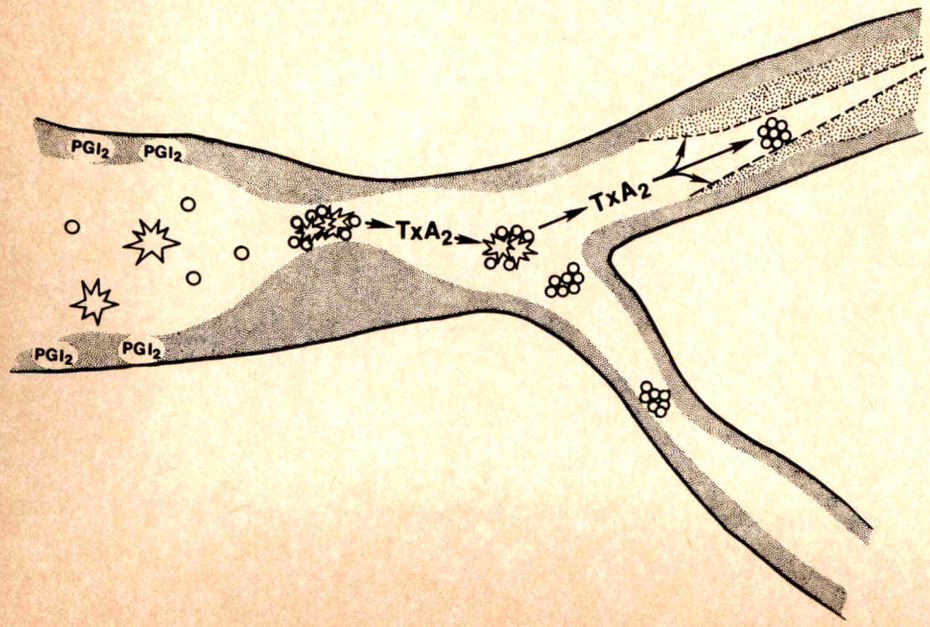

FIGURE 4. Schematic representation of manner in which episodic platelet aggregation may occur at the site of severe coronary arterial narrowings, causing unstable angina pectoris. Actively aggregating platelets accumulate at site of a stenosis, releasing thromboxane TxA_2, a powerful promoter of platelet aggregation. Periodically, these platelet aggregates fragment and move distally past severe stenosis, where they lodge in smaller arterioles and capillaries. **Open circles** designate platelets; **stars,** aggregated platelets. Reproduced with permission from *Am J Med.*[27]

and the dosage administered, as well as the magnitude of decrease in afterload, which, if prominent, may mask a negative inotropic effect. With reductions in afterload, there may be an increase in sympathetic tone, such that cardiac output is unchanged or increases slightly; heart rate may also increase reflexly.[31–34]

Verapamil has been used for the treatment of ischemic heart disease and supraventricular tachyarrhythmias since the 1960s.[32,35–37] It is well absorbed orally, but its bioavailability is reduced substantially by first-pass metabolism in the liver.[38] The daily dosage of verapamil ranges from 240 to 480 mg administered in 3 to 4 doses. Total dosage as high as 720 mg/day has been used without adverse effects. Hemodynamic effects from oral verapamil are evident at 1 to 2 hours and the peak effect is 4 to 5 hours after its administration. The excretion of verapamil is primarily renal.

Adverse effects from verapamil administration may include marked bradycardia; AV block; peripheral vasodilation leading to hypotension, headache or dizziness; and reduced intestinal smooth muscle motility leading to constipation.[1,13,39–42] Thus, verapamil should be given with caution to the patient with sinus bradycardia, "sick sinus syndrome," AV block or left ventricular (LV) dysfunction. In addition, patients with LV failure or heart block should not receive concomitant therapy with β-adrenergic blockers or disopyramide, because this combination may cause profound heart failure or AV block. The overall incidence of adverse effects is 9 to 10%, but severe reactions requiring discontinuation of verapamil occur in only 1% of patients.[43]

Nifedipine is a potent vasodilator that is particularly effective in the treatment of patients with ischemic heart disease or systemic arterial hypertension.[3,44,45] In addition, it has been used as an unloading agent in patients with severe LV failure,[46] and it may reduce pulmonary arterial pressure and resistance in patients with pulmonary hypertension.[47,48] Unlike verapamil, nifedipine exerts no effect on cardiac conduction and, therefore, is not useful in the treatment of supraventricular tachyarrhythmias. Its absorption is nearly complete after oral or sublingual administration; the onset of action is within 20 minutes of an oral dose and within 5 minutes when given sublingually.[49] The duration of effect is 8 to 12 hours, and the usual oral dose is 10 to 40 mg every 6 to 8 hours; dosages up to 160 mg/day have been used safely. Its excretion is primarily renal.[49] Adverse effects, including headache, dizziness, flushing and dysesthesias, occur in up to 40% of patients but are sufficiently severe to require its discontinuation in only about 5%.[50,51]

Diltiazem is useful in patients with ischemic heart disease, and it may also be effective in those with supraventricular tachyarrhythmias.[52–54] Like verapamil, diltiazem impairs AV conduction and decreases the rate of sinus nodal impulse formation. Therefore, concomitant use with β-adrenergic blockers may be hazardous in the person with sinus bradycardia or conduction system disease. Diltiazem is well absorbed orally, with daily dosage of 180 to 360 mg administered in 3 to 4 doses. Its onset of action is within 30 minutes of its administration, and it has a plasma half-life of 4 hours.[55] In contrast to verapamil and nifedipine, its excretion is primarily hepatic. Adverse effects are uncommon and include headache, dizziness, flushing, gastrointestinal disturbances and skin rash.

Table I lists the clinical and pharmacologic considerations relevant to the administration of these 3 agents.

Clinical Applications

Prinzmetal's (variant) angina pectoris: Blinded and randomized comparisons of verapamil and placebo have demonstrated this calcium blocker's beneficial effect in decreasing the frequency of chest pain, nitroglycerin usage and episodes of transient ST-segment deviation (Fig. 6).[13,56–58] Similarly, nifedipine is efficacious in decreasing the frequency of pain in patients with this clinical problem.[50,59–61] In patients with this syndrome given open-label nifedipine (40 to 160 mg/day), the frequency of anginal episodes was markedly decreased, with a complete relief of angina in nearly two thirds and a diminution of anginal frequency by ≥50% in almost all patients.[50] Diltiazem has been evaluated in 2 blinded studies of 10 to 12 weeks' duration encompassing 25 patients with Prinzmetal's angina.[52,53] In comparison to placebo, diltiazem (240 mg/day) caused a significant decrease in the frequency of chest pain and nitroglycerin usage.

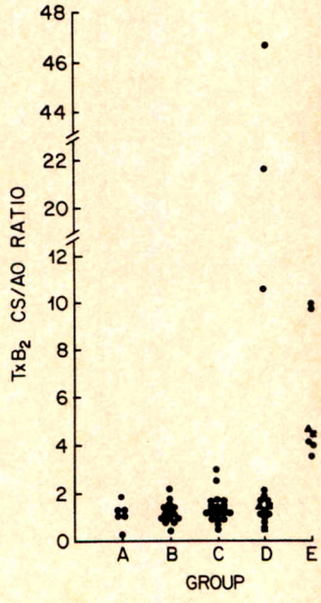

FIGURE 5. Ratios of coronary sinus (CS) to ascending aortic (AO) thromboxane B_2 (TxB_2) values in 5 groups of patients with various kinds of heart disease: group A (valvular and congenital nonischemic heart disease), group B (chest pain without ischemic heart disease), group C (ischemic heart disease without chest pain for >96 hours), group D (ischemic heart disease and chest pain within 24 to 96 hours of study) and group E (ischemic heart disease and chest pain within 24 hours of study). Those with continuing unstable angina (group E) have higher ($p < 0.05$) CS/AO TxB_2 ratios than other groups. Reproduced with permission from *N Engl J Med.*[16]

TABLE I Clinical Aspects of Calcium Antagonists

Drug	Dosage	Uses	Adverse Effects	Precautions
Verapamil	IV 0.075–0.150 mg/kg oral 80–120 mg every 6–8 hours	Supraventricular tachyarrhythmias Hypertrophic cardiomyopathy Variant angina pectoris Stable (exertional) angina Unstable angina at rest ? Protection of ischemic myocardium	Hypotension, headache, dizziness, pedal edema, constipation, AV nodal block	Use with β blockers may produce AV nodal block and/or LV dysfunction Use with disopyramide may cause LV dysfunction Use in digitalis excess or sick sinus syndrome may result in AV nodal block
Nifedipine	Oral or SI 10–40 mg every 6–8 hours	Systemic hypertension Variant angina pectoris Stable (exertional) angina Unstable angina at rest ? Protection of ischemic myocardium Unloading agent in patients with CHF Pulmonary hypertension	Hypotension, headache, flushing, pedal edema, dizziness	Use with β blockers generally safe Rarely may produce marked hypotension and increased angina
Diltiazem	Oral 30–90 mg every 6–8 hours	Stable (exertional) angina Variant angina pectoris ? Unstable angina at rest	Headache, dizziness, flushing, skin rash	Use with β blockers not evaluated but may result in AV nodal block or sinus bradycardia

AV = atrioventricular; CHF = congestive heart failure; IV = intravenous, LV = left ventricular; SI = sublingual.
Adapted from Winniford et al.[1]

There is little information concerning the relative efficacies of the slow-channel calcium antagonists in patients with Prinzmetal's angina. In 23 patients with this syndrome, we have shown that nifedipine and verapamil produce similar reductions in the frequency of chest pain, nitroglycerin usage, and ST-segment deviations (recorded by ambulatory electrocardiographic monitoring) (Fig. 7).[62] Studies from Japan suggest that nifedipine (30 to 60 mg/day) and diltiazem (90 to 240 mg/day) may be more effective than verapamil (120 to 320 mg/day) in treating variant angina, but these drugs were not compared directly in the same patients, and optimal doses of each were not administered.[63]

Unstable angina pectoris: The optimal medical therapy for the patient with unstable angina is controversial, but several studies have suggested that the slow-channel calcium antagonists may relieve angina in many of these patients.[64–70] In blinded, placebo-controlled evaluation, we and others have shown that verapamil significantly decreases the frequency of chest pain, nitroglycerin usage and ST-segment deviations (Fig. 8).[64,69] Other studies have shown that nifedipine (in doses of 40 to 80 mg/day) causes a significant decrease in anginal frequency when given to patients with continuing pain despite traditional antianginal therapy (Fig. 9).[70] However, Muller et al[71] have recently shown that nifedipine therapy alone is no better than conventional therapy in the treatment of patients with unstable angina pectoris. In a relatively small number of patients with unstable angina, diltiazem has been shown effective, especially in those whose angina is associated with transient ST-segment elevation.[68] Thus, the slow-channel calcium antagonists are efficacious in patients with unstable angina, particularly those in whom coronary arterial spasm is of etiologic importance.

Protection of ischemic myocardium: During prolonged ischemia and with acute myocardial infarction, the sarcolemmal membrane develops permeability defects to calcium that allow the intracellular calcium concentration to increase.[72–75] The development of these defects appears to correlate with loss of certain phospholipids from the sarcolemmal membrane and with structural defects in the sarcolemma.[72–75] In addition, sodium-calcium exchange may lead to cellular loading with calcium during both prolonged ischemia and temporary ischemia followed by reperfusion.[76] As the intracellular calcium concentration increases, the mitochondria sequester excessive amounts. As a result, mitochondrial oxidative phosphorylation is impaired, and less adenosine triphosphate (ATP) is available for normal metabolic processes, including maintenance of the structural integrity of the sarcolemmal membrane.[77] The entry of calcium into the myocardial cells also activates phospholipases capable of causing additional sarcolemmal damage and irreversible cellular injury.[77] Thus, irreversible cell injury during severe and prolonged myocardial ischemia and with myocardial infarction probably occurs because of structural and biochemical alterations to the sarcolemmal membrane that allow the loss of intracellular constituents and

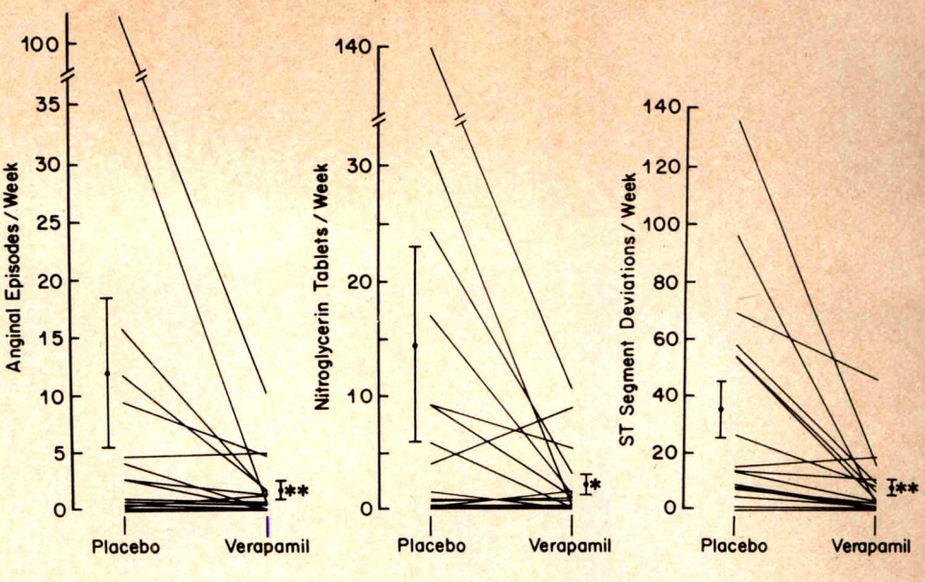

FIGURE 6. Number of anginal episodes per week (**left**), nitroglycerin tablets consumed per week (**middle**) and transient ST-segment deviations on calibrated 2-channel ambulatory electrocardiographic monitoring (**right**) in 16 patients with variant angina pectoris during therapy with placebo or verapamil. Each line represents data from 1 patient, and mean ± standard error of mean is shown on either side of each group of lines. Verapamil diminished all 3 variables ($p < 0.05$). Reproduced with permission from *N Engl J Med.*[13]

unrestricted entry of calcium and other usually extracellular ions. Whether the unrestricted entry of calcium intracellularly is a critical event in the development of irreversible cellular injury remains a controversial issue.

Because 1 route of transsarcolemmal calcium entry into the cell is through slow-calcium channels, pharmacologic antagonism of slow-channel calcium transport during myocardial ischemia may help to reduce the intracellular calcium concentration, thereby prolonging cell viability. However, this is probably effective only for brief periods of ischemia, because generalized alterations in membrane permeability and structural defects in sarcolemmal membranes occur with severe and prolonged ischemia and with myocardial infarction. Nevertheless, with short periods of myocardial ischemia, slow-channel calcium antagonists may help to protect injured myocytes by increasing coronary blood flow to the ischemically injured cells, by reducing myocardial oxygen demand and, potentially, by diminishing total cellular calcium burden in the injured cells.

In the experimental animal, nifedipine increases collateral perfusion of ischemic myocardium and reduces the extent of myocardial injury, particularly at sites that are only mildly injured.[78–80] Verapamil may reduce ischemic-induced contracture, mitochondrial calcium accumulation and infarct size.[81–83] Diltiazem decreases reperfusion-induced injury after temporary arterial occlusion and, in combination with propranolol, protects LV segmental function at moderately injured sites.[84–86] Thus, in the experimental animal, selected calcium antagonists given before or soon after short periods of coronary arterial occlusion or temporary coronary occlusion and reperfusion may protect segmental LV function and reduce the extent of myocardial injury. However, Urquhart et al[87] have demonstrated different potencies during acute myocardial ischemia in canine models for verapamil, diltiazem and nifedipine on LV function and heart rate when compared with their relative vasodilator capabilities.

It is not yet clear whether calcium antagonists possess the ability to reduce infarct size and preserve ventricular function during acute myocardial infarction associated with permanent or temporary coronary arterial occlusion followed by reperfusion in man. However, the initial evaluations of selected calcium antagonists administered during evolving myocardial infarction are not terribly encouraging.[88–90] In a double-blind, multicenter Norwegian study, 227 patients with suspected acute myocardial infarction received nifedipine or placebo within 12 hours of onset of symptoms.[88] Ni-

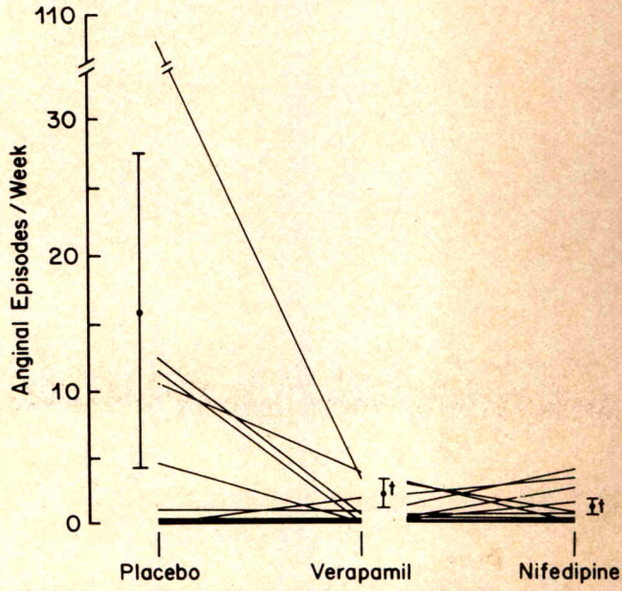

FIGURE 7. Number of anginal episodes per week during therapy with placebo (**left**), verapamil (**middle**) and nifedipine (**right**) in 10 patients with Prinzmetal's angina pectoris. Each line represents data from 1 patient, and mean ± standard error of mean is shown on either side of the lines. Compared with placebo, verapamil and nifedipine reduced frequency of angina. Reproduced with permission from *Am J Cardiol.*[62]

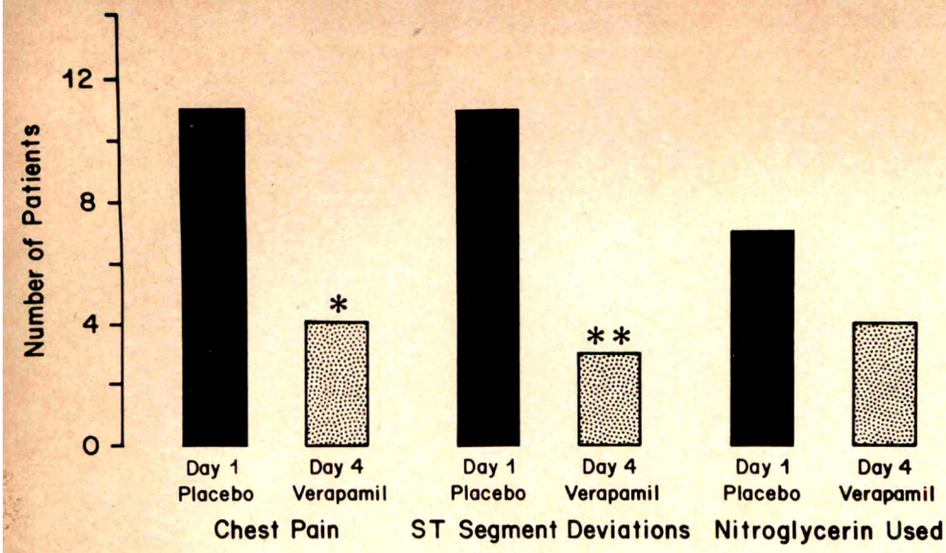

FIGURE 8. Number of patients with chest pain (**left**), ST-segment deviation (**middle**) and nitroglycerin usage (**right**) on day 1 (placebo) and day 4 (verapamil) in 11 patients hospitalized with severe unstable angina pectoris. Verapamil reduced chest pain and ST-segment deviation but not number of nitroglycerin tablets consumed. Four patients continued to have chest pain during verapamil therapy, and 3 patients continued to have transient ST-segment deviations. Reproduced with permission from *Am Heart J.*[69]

fedipine failed to reduce infarct size as measured by creatine kinase-MB (CK-MB) infarct size determinations.[88] Similarly, Muller et al[89] were unable to demonstrate that nifedipine reduced the frequency or size of acute myocardial infarction in a randomized study of 110 patients given either nifedipine (20 mg orally every 4 hours for 14 days) or placebo within a mean of 5.2 ± 2.5 (standard error) hours after the onset of chest pain. However, data from Bussman et al[90] suggest that intravenous verapamil given within 8 hours and continued for 2 days postmyocardial infarction may reduce infarct size, as measured by CK and CK-MB, by approximately 30% in patients. Each of these studies evaluated relatively small numbers of patients without reperfusion and relatively late after myocardial infarction. It remains to be determined conclusively whether a selected calcium antagonist may reduce infarct size and preserve ventricular function when given relatively early after the onset of symptoms or when administered during reperfusion associated with thrombolytic therapy or both.

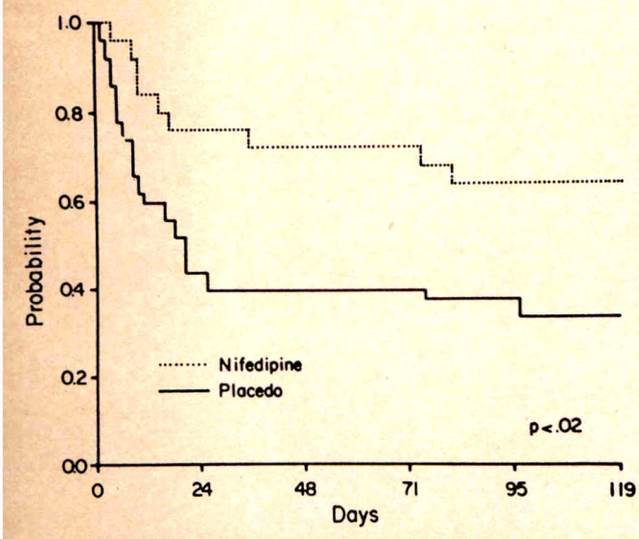

FIGURE 9. Effect of nifedipine on efficacy of medical therapy in patients with ST-segment elevation during unstable angina pectoris over a 119-day follow-up period. Compared with placebo, nifedipine significantly increased the likelihood that medical therapy was effective during this period of followup. Reproduced with permission from *N Engl J Med.*[70]

Use of Nifedipine to Decrease Ischemic-Reperfusion Injury in the Surgical Setting

RICHARD E. CLARK, MD, IGNACIO Y. CHRISTLIEB, MD, JOHN C. VANDERWONDE, MD, and PHILIP D. HENRY, MD

This report summarizes studies that provided a basis for a randomized clinical trial of nifedipine in cold hyperkalemic cardioplegic solution. Data from normothermic, isolated working rabbit heart studies demonstrated that presence of micromolar concentrations of nifedipine in the perfusate during continuous low flow or nifedipine used as bolus washouts during global ischemia prevented increases in systolic and diastolic stiffness, which could be related to dose and prevention of intracellular accumulation of calcium. Other studies in open-chest dogs in whom regional ischemia was produced showed that nifedipine was superior to sodium nitroprusside when infused during the ischemic and reperfusion intervals with respect to preservation of hemodynamic variables and reduction of myocardial injury. Further, data from cardiopulmonary bypass experiments in dogs conducted at myocardial temperatures of 37, 28, 18 and 12°C with 1, 2 and 3 hours of global ischemia all demonstrated significant efficacy.

To date, the randomized clinical trial has shown a small reduction in the incidence of low cardiac output syndrome in high-risk patients. Those receiving nifedipine had improved hemodynamic variables. No patient in the treated group had myocardial injury in the postoperative interval shown by radionuclide pyrophosphate scan. The conclusions from this trial are that nifedipine was efficacious when included in a cold hyperkalemic cardioplegic solution. The responses observed, however, appear to be dose-, vehicle- and species-dependent.

(Am J Cardiol 1985;55:125B–138B)

Chemical cardioplegia for preservation of ischemic myocardium during cardiac surgery has been in use for 25 years.[1] During this interval, a few basic principles for myocardial preservation have evolved. First, hypothermia is a potent protective agent.[2–7] Second, it is essential to prevent rapid degradation of high-energy phosphate compounds by immediate cessation of electrical and mechanical activity of the heart concomitant with the onset of global ischemia.[8–12] Third, the functional result obtained after ischemia and reperfusion is strongly related to the preischemic biochemical and morphologic status of the heart and the duration and temperature during the ischemic period.[13–16] Fourth, during the initial minutes of the reperfusion period, the myocardium is highly susceptible to further injury, but the mechanisms governing further injury or recovery during this interval are incompletely understood.[17–20] Finally, the chemical composition of the solution, the frequency and volume administered and the rate of delivery are highly important to the degree of preservation achieved.[13,21–26]

Early in the ischemic process, an increase in intracellular calcium (Ca^{++}) concentration results in inappropriate activation and impairment of synthesis of adenosine triphosphate. There is an accelerated depletion of high energy stores paralleled by impaired myocardial relaxation. During the initial reperfusion phase, flooding of the cell by Ca^{++} may occur and lead to myocardial rigor, a state that has been termed the "stone heart." Myocardial reperfusion after temporary ischemia[27] or perfusion with Ca^{++}-free perfusate[28] has been reported to result in accumulations of intracellular Ca^{++} and in explosive deteriorations in myocardial structure and function. Calcium deposits have also been described in the cardiac lesions produced by the administration of large amounts of catecholamines[29] and in the cardiomyopathy of the Syrian hamster.[30]

Fleckenstein[31] and collaborators were the first to delineate a group of compounds they referred to as Ca^{++} antagonists, which inhibited the contractile activity of cardiac and smooth muscle by blocking the inward movement of Ca^{++} into cells. Fleckenstein[29] further demonstrated that pretreatment with the Ca^{++} antagonists verapamil and D-600 protected rats from catecholamine-induced cardiac necrosis and Ca^{++} accumulation and Syrian hamsters from the development of their genetically determined cardiomyopathy.

The studies summarized herein covered a 7-year period[32–40] and provided the basis for the initiation of a clinical trial of nifedipine in cardioplegic solution. The rationale was that prevention of the abnormal accumulation of intracellular Ca^{++} during ischemia and reperfusion could be ameliorated with the use of a Ca^{++} antagonist, which would result in less of a depletion of high-energy phosphate stores, less of an increase in stiffness and less of a decrease in contractility. We chose nifedipine because previous studies demonstrated it has the potential to exert protective effects on the myocardium.[18,32,33]

Normothermic Isolated Perfused Heart Preparation—Low Flow Studies

Rabbit hearts were isolated and perfused retrograde at 37°C through the aorta as previously described.[9] The perfusate was a modified Krebs-Henseleit solution equilibrated with a 5% carbon dioxide-95% oxygen gas mixture. The pH was approximately 7.4. The rate of perfusion was maintained at 22 ml/min with a roller pump. A latex balloon mounted around a micromanometer (Konigsberg model P3.5) was inserted into the left ventricular (LV) cavity for measurement of LV pressure and its first-time derivative (dP/dt). The heart was paced at 180 beats/min. The major determinants of cardiac performance were controlled. All hearts were equilibrated for 30 minutes at a flow rate of 22 ml/min. Then, slow perfusion (0.2 ml/min; 5 ml/100 g fresh myocardium/min) with perfusate containing nifedipine or its vehicle was started and maintained for 60 minutes. The drug, or its vehicle in control experiments, was infused with a syringe pump into the perfusion system at a rate not exceeding 1% of the total flow. In some experiments, high flow (22 ml/min) without nifedipine was reinstituted (reperfusion) at the end of the slow flow interval. In other experiments, hearts at the end of perfusion were used to determine the ventricular wet weight/dry weight ratio. The Ca^{++} content of the mitochondrial fraction was assayed and used as an index of cell Ca^{++}. This approach is based on the finding, which has been described in detail previously,[18] that most of the Ca^{++} accumulating in ischemic myocardium is recovered in the mitochondria and mitochondrial cristae.

A representative record of an isovolumic left-side heart preparation subjected to 60 minutes of low flow (0.2 ml/min) is illustrated in Figure 1, top panel. Once ischemic standstill had occurred, the ventricle had progressive ischemic contracture. Ventricular pressure at the end of the ischemic period exceeded 50 mm Hg. With subsequent reperfusion, end-diastolic pressure remained markedly increased, which indicated persistent myocardial stiffness. In addition, the heart was arrhythmic despite ventricular pacing. Figure 1, bottom, shows the response of a heart subjected to exactly the same protocol except that nifedipine (10^{-7} M) was added to the perfusate during (but not before or after) low flow. As in the control experiment, there was a precipitous decrease in cardiac contractility followed by ventricular standstill. However, in sharp contrast to the control experiments, no contracture developed. Furthermore, with reperfusion, end-diastolic pressure (EDP) remained low, and there was a striking recovery

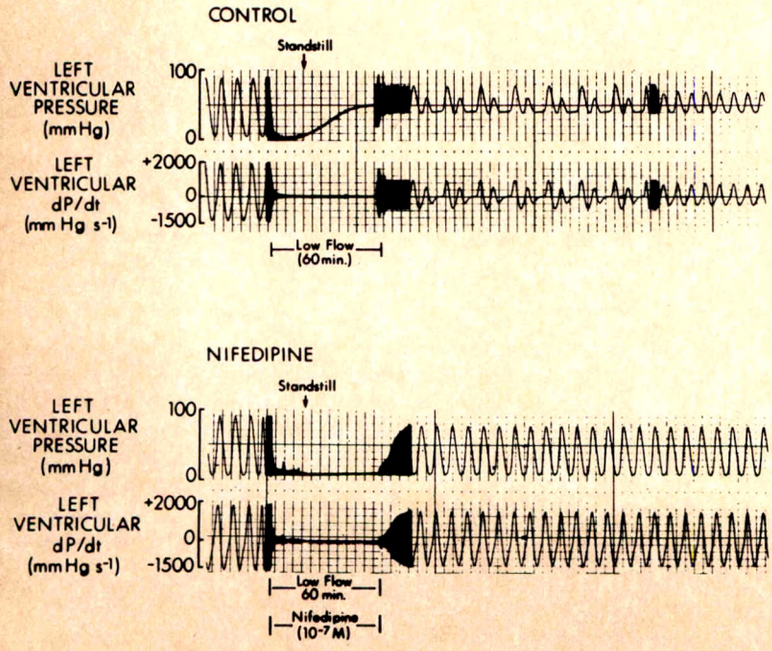

FIGURE 1. Inhibition of ischemic ventricular contracture by nifedipine. Perfusion experiments with paced isovolumic left heart preparations were performed as described in the text. Standstill refers to no visible ventricular activity and no pulsatile pressure on tracings recorded with a second recorder at paper speed of 25 mm/s and full scale of 100 mm Hg. Low flow refers to rate of perfusion of 0.2 ml/min. Fast and slow (**black areas**) segments of tracings were recorded at paper speed of 25 mm/s and 1 mm/min, respectively. dP/dt = first derivative of left ventricular pressure. Reprinted with permission from Raven Press. In: Winbury MM, Abiko Y, Eds. *Ischemic Myocardium and Antianginal Drugs*. New York: Raven Press, 1979.

in developed pressure and dP/dt. Results of the experiments depicted in Figure 1 are diagrammatically summarized in Figures 2 and 3. Results of measurements of calcium, copper and protein in perfused hearts and in hearts processed immediately after sacrifice of the animal are summarized in Table I. Perfusion at high flow resulted in only a minor increase in mitochondrial Ca^{++}. Sixty minutes of low flow without nifedipine increased the Ca^{++} value more than 4-fold, and subsequent reperfusion for 10 minutes produced a further marked increase. In contrast, in nifedipine-treated hearts subjected to low flow with or without reperfusion, accumulation of Ca^{++} in the mitochondrial fraction remained modest.

Figure 4 shows the relation between myocardial stiffness, as reflected by the nonpulsatile ventricular pressure at the end of the low-flow period (contracture pressure) or by the EDP after 10 minutes of reperfusion, and accumulation of Ca^{++} in the mitochondrial fraction. Increasing myocardial stiffness was associated with increasing Ca^{++} values, and reperfusion enhanced the accumulation of Ca^{++}. Treatment with nifedipine prevented ischemic myocardial stiffness as well as Ca^{++} accumulation.

Global Ischemia in an Isolated Heart Preparation: Determination of Dose-Response Relations

The empiric addition of agents to cardioplegic solutions may be harmful at certain concentrations and beneficial at others. We conducted the following experiments to develop a stable, isolated heart preparation of global ischemia with which to assess dose-response relations of calcium-channel blockers. The preparation was designed to allow measurement of both LV pres-

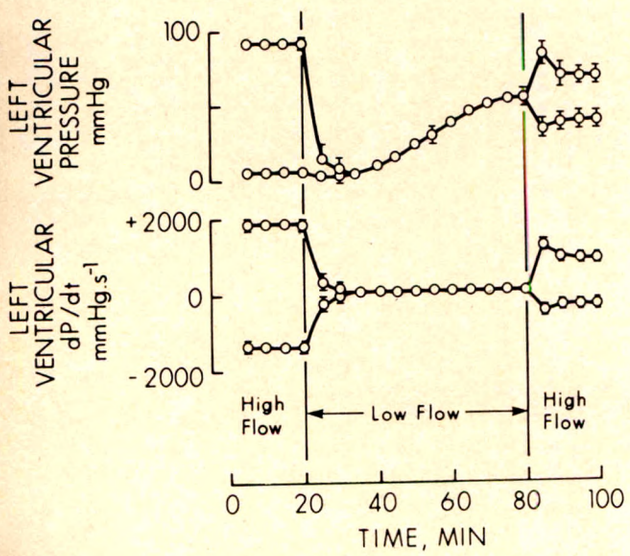

FIGURE 2. Ischemic contracture in isovolumic left heart preparations (n = 8). Perfusions were performed as described in the text and illustrated in Figure 1, top. High and low flow refer to flow of 22 and 0.2 ml/min, respectively. Buffer during low flow contained <0.1% of the vehicle of nifedipine (final ethanol and polyethylene glycol concentrations both <0.015%). Data points indicate mean ± standard error. dP/dt = first derivative of left ventricular pressure. Reprinted with permission from Raven Press. In: Winbury MM, Abiko Y, Eds. *Ischemic Myocardium and Antianginal Drugs*. New York: Raven Press, 1979.

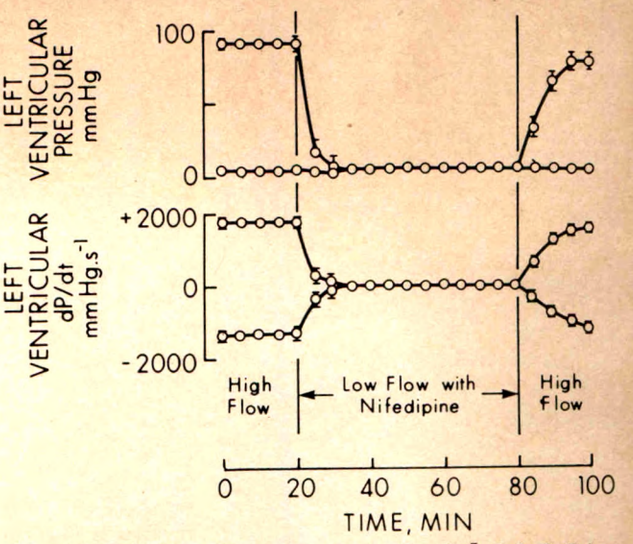

FIGURE 3. Inhibition of ischemic contracture by 10^{-7} *M* of nifedipine (n = 8). Experiments were performed exactly as described in the text and illustrated in Figure 1, except that the vehicle contained nifedipine to yield final drug concentration of 10^{-7} *M*. No nifedipine was administered before or after period of low flow. Data points indicate mean ± standard error. Reprinted with permission from Raven Press. In: Winbury MM, Abiko Y, Eds. *Ischemic Myocardium and Antianginal Drugs*. New York: Raven Press, 1979.

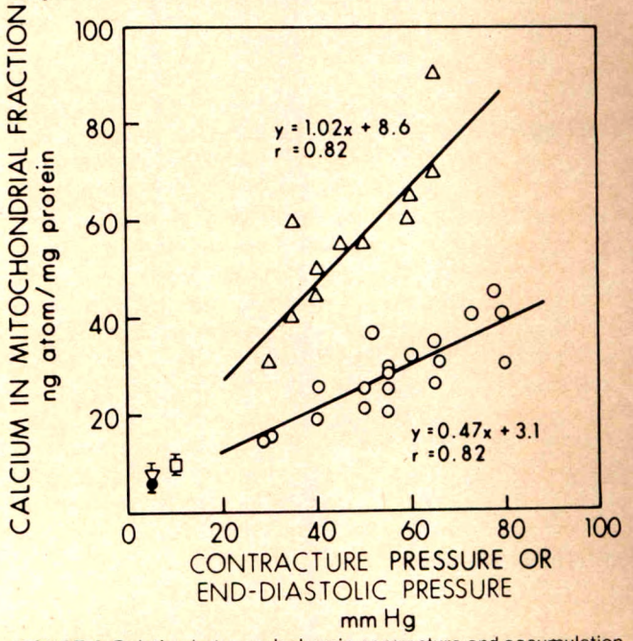

FIGURE 4. Relation between ischemic contracture and accumulation of calcium in the mitochondrial fraction. Perfusions were performed as described in the text. Mitochondrial fractions were prepared with solutions containing ruthenium red. **Solid circle with bars:** after a standard equilibration period, hearts were perfused at 22 ml/min for 60 minutes with buffer containing no nifedipine (n = 7). **Open inverted triangle with bars:** perfusions at low flow (0.2 ml/min) for 60 minutes with buffer containing nifedipine (10^{-7} *M*) and its vehicle (n = 9). **Open square with bars:** after a 60-minute period of low flow with nifedipine, hearts were reperfused at 22 ml/min for 10 minutes with buffer containing no nifedipine (n = 10). **Open circles:** 60-minute perfusions at low flow with buffer containing vehicle without nifedipine. **Open triangles:** 60 minutes of low flow with buffer containing vehicle without nifedipine, followed by 10 minutes of reperfusion. Data points represent mean ± standard error and are from the same experiments as summarized in Figures 2 and 3 and Table I. Reprinted with permission from Raven Press. In: Winbury MM, Abiko Y, Eds. *Ischemic Myocardium and Antianginal Drugs*. New York: Raven Press, 1979.

TABLE I Calcium and Copper in Mitochondrial Fraction*

	Hearts (n)	Calcium ng atom (mg protein)	Copper ng atom (mg protein)	Calcium/ Copper	Copper in mitochondrial fraction (%)	Protein in mitochondrial fraction (%)
No perfusion†						
−N	8	6.2 ± 0.3	1.37 ± 0.05	4.53 ± 0.23	10.9 ± 0.4	4.01 ± 0.22
+N	8	6.3 ± 0.3	1.36 ± 0.06	4.63 ± 0.24	11.4 ± 0.5	4.12 ± 0.23
−R	7	6.8 ± 0.4	1.38 ± 0.04	4.93 ± 0.29	10.7 ± 0.4	4.10 ± 0.19
60 minutes high flow‡						
−N	7	7.6 ± 0.4	1.38 ± 0.06	5.51 ± 0.41	11.6 ± 0.5	4.21 ± 0.25
+N	8	7.4 ± 0.4	1.34 ± 0.06	5.52 ± 0.43	12.0 ± 0.7	4.05 ± 0.28
60 minutes low flow§						
−N	10	28.2 ± 1.9	1.41 ± 0.05	19.9 ± 1.61	9.2 ± 0.9	3.41 ± 0.21
+N	10	8.0 ± 0.5	1.30 ± 0.07	6.15 ± 0.55	10.8 ± 0.7	4.15 ± 0.27
60 minutes low flow + 10 minutes reperfusion‖						
−N	11	55.5 ± 4.8	1.29 ± 0.09	42.65 ± 3.9	6.8 ± 0.7	2.52 ± 0.21
+N	12	10.0 ± 0.6	1.33 ± 0.10	7.52 ± 0.63	9.4 ± 0.7	3.50 ± 0.24
−R	9	58.6 ± 6.0	1.31 ± 0.12	44.73 ± 4.8	6.2 ± 0.8	2.31 ± 0.30

* Percentages of copper or protein in the mitochondrial fraction are expressed as percentages of the total myocardial copper or protein in the whole homogenate. Values are mean ± standard error.

† No perfusion: hearts processed immediately after killing the animal without Langendorff perfusion; in these preparations, −N and +N refer to the absence or presence, respectively, of 10^{-7} *M* nifedipine in the preparative solutions, and −R indicates that ruthenium red was omitted from all preparative solutions.

‡ High flow: perfusion at 22 ml/min; in perfused hearts, −N and +N refer to the addition of vehicle alone or vehicle plus nifedipine (10^{-7} *M*), respectively, to the perfusate during the experimental perfusion period (60 minutes).

§ Low flow: perfusion at 0.2 ml/min; −N and +N as in high flow.

‖ Reperfusion: −R indicates that perfusion was carried out without nifedipine and that ruthenium red was omitted from all preparative solutions; −N and +N, as in high flow and low flow. Reprinted with permission from Raven Press. In: Winbury MM, Abiko Y, Eds. *Ischemic Myocardium and Antianginal Drugs*. New York: Raven Press, 1979.

sures and flow without an apex puncture or use of an isovolemic balloon. The use of rabbit hearts served a 2-fold purpose: avoidance of an excessive number of costly canine experiments in the initial screening for dose responses and avoidance of the rat heart, given its known species-specific resistance to digitalis glycosides and other anomalous cardiac responses.

Dual perfusion circuits and hearts (over 230) isolated from New Zealand White rabbits (2.5 ± 0.3 kg) were used. After intravenous heparin (500 μ/kg) and pentobarbital (60 mg/kg) anesthesia, hearts were excised and mounted on an isolated working heart apparatus. A unique dual lumen-left atrial cannula provided access for anterograde flow and high-fidelity measurement of LVEDP and positive and negative dP/dt. At constant heart rate and mean aortic pressures, LV function curves were developed relating stroke work indexes (SWIs) to LVEDP. Coronary flow indexes per gram of heart weight, myocardial oxygen consumption ($M\dot{V}O_2$) and developed LV pressure were measured as the function curves were generated. One hundred hearts were perfused in development of the technique. A Krebs-Henseleit albumin perfusate allowed 3 hours of continuous work with minimal deterioration (Control group C-1). Two additional control groups (C-2 and C-3) and 2 cardioplegic solution groups (cardioplegic solutions and cardioplegic solutions + nifedipine) were studied at 38 ± 0.5°C. Group C-2 (n = 17) was given rapid volume loading at 5 and 115 minutes of perfusion to assess performance as a function of time. Group C-3 (n = 10) was given 30 minutes of global ischemia and reperfusion to assess effects of unaltered ischemia on the preparation. Hearts given cardioplegic solution (n = 32) and cardioplegic solutions + nifedipine (n = 12) had two 10-ml aortic root injections of cardioplegic solutions (potassium = 27 m*M*) at 0 and 15 minutes of global ischemia. Nifedipine was added to cardioplegic solutions in a concentration found effective in dog and man (0.2 μg/ml). In other studies (n = 25), nifedipine was added in doses of 0.01 to 0.40 μg/ml to define dose-response relations. Data were analyzed by analysis of variance.

The results of groups of C-2, C-3, cardioplegic solutions and cardioplegic solutions + nifedipine are summarized in Table II. This preparation had stable SWI and $M\dot{V}O_2$ and negative dP/dt over 2 hours of perfusion (difference is not significant [p = NS]) with time-related degradation of coronary flow indexes, positive dP/dt and developed LV pressure (all $p < 0.001$) to a level of 90 to 95% of preischemic values. In group, C-3, 30 minutes of unaltered global ischemia resulted in ischemic contracture in 60% of the hearts. In groups given cardioplegic solutions, all measurements of cardiac function were decreased from preischemic values ($p < 0.001$). The addition of nifedipine produced an amelioration of decreased function.

Whereas cardioplegic solutions without nifedipine resulted in a 45% decrease in SWI, the addition of nifedipine yielded a 17% decrease ($p < 0.05$) and $M\dot{V}O_2$ was equal to the preischemic value. Further, there was marked improvement in the postischemic coronary flow indexes ($p \leq 0.01$) and negative dP/dt ($p \leq 0.05$). Doses of nifedipine <0.10 μg/ml were not effective and doses of >0.4 μg/ml were harmful.

Regional Ischemia in Open-Chest Dogs

One hundred twelve mongrel dogs were anesthetized, intubated and ventilated, and had left thoracotomies. Phasic and mean pressures were recorded through

Values are mean ± standard error of the mean.
CFI = coronary flow index; CPS = cardioplegic solution; CPS + N = cardioplegic solution plus nifedipine; DLVP = developed left ventricular pressure; +dP/dt = positive first derivative of left ventricular pressure; −dP/dt = negative first derivative of left ventricular pressure; GI = global ischemia; LVEDP = left ventricular end-diastolic pressure; O_2Con = oxygen consumption; SWI = stroke work index.

catheters placed in the right atrium, ascending aorta, left atrium and left ventricle. An electromagnetic flow probe was applied to the ascending aorta for determination of plastic and mean flows. The LV pressure was differentiated and recorded directly as dP/dt. Occlusion of the left anterior descending coronary artery was accomplished with fine silicone rubber tubing. Animals were treated with aortic root infusions during the ischemic period of 1 or 2 hours duration, during the 2-hour reperfusion period (which was constant for all animals) or during both periods. Each animal had an infusion of either saline solution or saline solution plus sodium nitroprusside or nifedipine at a rate of 40 ml/h through an aortic root needle controlled by an infusion pump. The solutions were at room temperature and the dosage of nifedipine was 5 μg/kg/hour at an average concentration of 3 mg/ml or nitroprusside 3 μg/kg/min. These dosages resulted in similar decreases in blood pressure. Infusions were begun simultaneously with occlusion or release of the left anterior descending coronary artery. After 120 minutes of reperfusion, 100 mg/kg of colloidal carbon was injected through the left atrial catheter. After 5 minutes the heart was flushed and fixed in situ. The heart was cut with a calibrated slicer in slices approximately 5 mm thick, perpendicular to the apical-aortic root axis. After complete fixation, each slice was photographed and the volume of the ischemic-reperfusion injury determined morphometrically; the results were expressed as a percentage of total volume.

The use of nifedipine during ischemia only or during the reperfusion interval was associated with marked improvements in SWI, dP/dt and cardiac index compared with animals given the same volume of saline solution or saline solution containing nitroprusside. The comparisons for 1 and 2 hours of regional ischemia are summarized in Tables III and IV. Nifedipine was most efficacious when given during both time intervals and it maintained SWI and dP/dt at control levels with little change in LVEDPs. In the 1- and 2-hour ischemic experiments, there was a 2- and 3-fold decrease in injury volume, respectively. The changes noted were significantly different from the saline solution-treated and the nitroprusside-treated animals ($p \leq 0.01$).

Global Ischemia Using Cardiopulmonary Bypass

Normothermic experiments: Mongrel dogs were anesthetized and placed on a volume-limited ventilator. After a right lateral thoracotomy, catheters and flow transducers were placed, as previously described. A metal cannula was inserted into a common femoral artery for perfusion from the heart-lung machine. Venous drainage cannulas were inserted through the azygos vein into the superior vena cava and through the right atrial appendage into the inferior vena cava. Rectal, myocardial and blood temperatures were measured with thermistors. Before cannulation of the vena cavae, each animal was given 500 to 600 ml of filtered citrate phosphate-dextrose preserved (≤24 hours) canine whole blood in rapid sequential 50 ml aliquots and LV function curve was characterized. Three- to 5-minute intervals were utilized for each measurement before bypass. After the initiation of partial cardiopulmonary bypass, an LV vent was inserted through the right superior pulmonary vein. The perfusate was maintained at a temperature of 37.5 ± 0.5°C. A 14-gauge plastic cannula was placed in the aortic root proximal to the flow transducer for infusion of various perfusate solutions to be described later.

After adjustment of the extra- and intracorporeal blood volumes with the animal on partial cardiopulmonary bypass, a clamp was applied to the ascending aorta and the heart was rendered ischemic. Simultaneously, an infusion of room temperature (23 to 27°C) solution at 4 ml/min was begun into the root of the aorta. In other experiments, bolus injections of 150 to 200 ml at 37°C or room temperature were made in 90 seconds and repeated every 30 minutes. Total body perfusion was maintained at a minimal flow rate of 100 ml/kg/min at a minimal mean aortic pressure of 70 mm Hg. No drugs were administered during perfusion. Crystalloid and colloid volume were added as required to meet the prescribed hemodynamic criteria.

After 1 hour of normothermic myocardial ischemia, the clamp on the ascending aorta was removed and the hearts were reperfused for 30 minutes under steady-state flow and pressure conditions. If necessary, the heart was then defibrillated. Attempts were made to

wean the animal from the extracorporeal circuit as quickly as possible. Blood volume was adjusted by infusion or withdrawal to maximize cardiac output. Once perfusion was discontinued, volume was added only when required to maintain a mean left atrial pressure similar to the average preischemic value. The animals were then observed for 2 hours without pharmacologic intervention.

Ventricular function was assessed by a comparison of variables measured directly and calculation of stroke volume, SWI and total peripheral resistance.

Hemodynamic data were evaluated statistically by both the paired and unpaired Student *t* tests. Each animal served as its own control for comparison of the preischemic and postischemic data (paired analysis). Preoperative and postoperative values for controls and experimental groups were compared by unpaired *t* test analysis. Pathologic studies were performed in a manner similar to that used for the regional ischemic experiments.

Solutions evaluated during normothermic global ischemic experiments: Three control solutions were used in 24 experiments: normal saline solution, normal saline solution with 25 mEq/liter of potassium chloride and Normosol®-pH 7.4. The first was used to study the influence of washout (continuous and intermittent) with

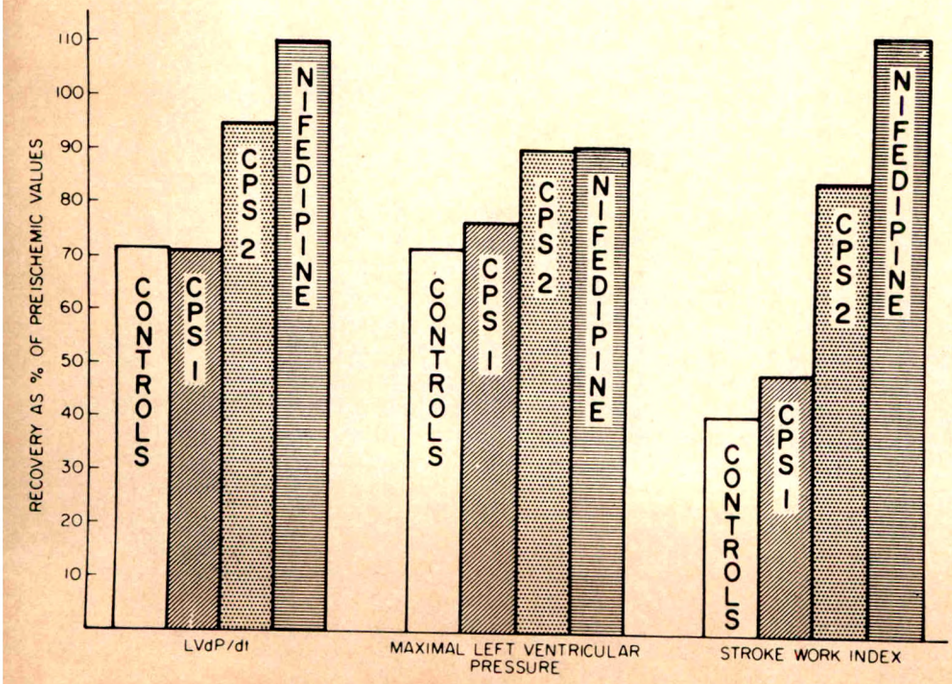

FIGURE 5. Recovery as a percentage of preischemic values is shown for left ventricular (LV) dP/dt, maximal LV pressure and stroke work index for groups of dogs given 1 hour of global ischemia at 37°C and treated with multiple doses of control solutions and extracellular-like cardioplegic solution (CPS 1) and intracellular-like cardioplegic solution (CPS 2) and saline and cardioplegic solutions containing 0.2 μg/ml of nifedipine (see Table IV for complete listing of hemodynamic variables). TPR (dynes s cm^{-5})	2,171 ± 321	2,196 ± 381	3,063 ± 296	2,273 ± 251	CPS II versus all other groups, p <0.05

* Mean ± standard error.
dP/dt = first derivative of left ventricular pressure; LVEDP = left ventricular end-diastolic pressure; LVP-MAX = maximum left ventricular pressure; MLAP = mean left atrial pressure; NS = not significant; TPR = total peripheral resistance.
For explanation of CPS I and CPS II, refer to text.

an isotonic pharmacologically inactive solution. The second was used as a control for the elevated potassium ion concentrations used in the 2 cardioplegic solutions tested. The third control solution was used because it was the base for 1 of the cardioplegic solutions and had a neutral pH in contrast to isotonic saline solution.

Two cardioplegic solutions were used in 31 experiments; one was an extracellular type and the second an intracellular type solution. Both had similar pH (7.7 to 7.8), osmolarity (340 to 360 mOsm/liter) and concentrations of potassium chloride, magnesium and lidocaine (25 mEq/liter, 3 mEq/liter and 250 mg/liter, respectively). The principal differences were in sodium ion concentrations (142 versus 28 mEq/liter), calcium (0 versus 0.6 mEq/liter), chloride (103 versus 28 mEq/liter) and substitution of Tham for sodium bicarbonate.

Nifedipine (0.167 to 0.20 μg/ml) was used in saline solution and in each of the 2 cardioplegic solutions in 23 experiments. Continuous infusions at 4 ml/min were tested in 48 experiments; multiple doses, given at a rate of 100 to 130 ml/min and a pressure of 90/100 mm Hg in the aortic root, were used in 30 studies.

The data for the various solution groups are summarized in Table V and Figure 5. At similar left atrial pressures and heart rates, the nifedipine-treated animals had greater LV stroke work indexes immediately after bypass than the cardioplegic-solution treated groups, which improved until the preischemic values were reached 2 hours after cessation of cardiopulmonary bypass (Fig. 6).

The differences in the functional capacity of the postischemic ventricle treated during ischemia with various solutions are demonstrated in Figure 7. Only those animals treated with the calcium antagonist responded in a normal manner to 50-ml incremental colloid volume infusions of 500 to 600 ml.

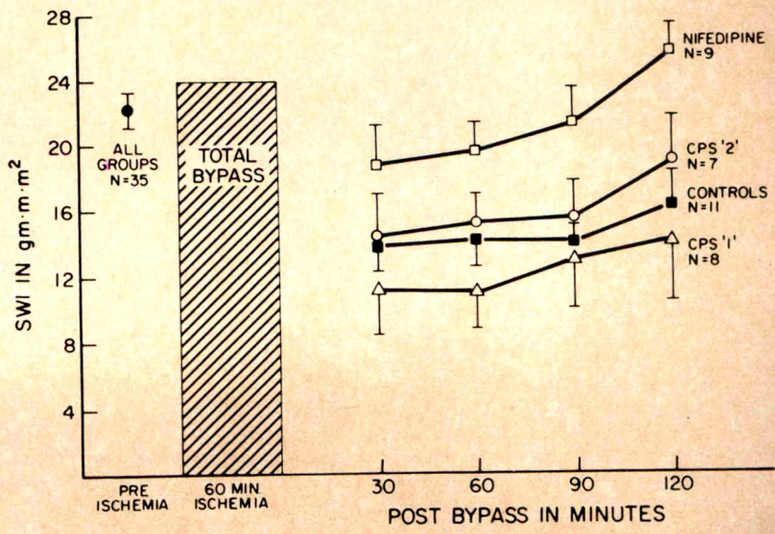

FIGURE 6. Stroke work index (SWI) versus event and time after bypass for 4 groups of dogs given 1 hour of global ischemia at 37°C and treated with multiple doses of control, 2 cardioplegic solution (CPS) and nifedipine solution. Reprinted with permission from *Ann Surg.*[39]

These data are for the bolus injection groups. The continuous infusion experiments demonstrated similar results, but recovery to preischemic levels was less in each subset than with the multidose mode of aortic root infusion.

Hypothermic experiments—1 or 2 hours of ischemia: Similar methods to those in the normothermic studies were used, with the following exceptions: 19 animals had global ischemia at 28°C for 1 hour (n = 5) and 2 hours (n = 14), and 24 dogs had global ischemia at an average myocardial temperature of 18°C for 1 hour (n = 6) and 2 hours (n = 18). The purpose of these studies was to ascertain the influence of 2 hypothermic myocardial temperatures frequently used in the clinical setting with 1 and 2 hours of ischemia on the degree of preservation conferred by control, cardioplegic and nifedipine solutions when given in multiple doses of 250 to 500 ml every 30 minutes. Solutions were at room temperature (30 ± 2°C) for the 28°C studies and 4°C for the 18°C studies. The solutions evaluated were control solutions of saline solution and Ringer's injection, the intracellular-like solution listed earlier, Ringer's injection containing 250 mg/liter of lidocaine, 27 mEq/liter of sodium bicarbonate and 25 mEq/liter of potassium chloride, and solution C containing 200 μg/liter of nifedipine.

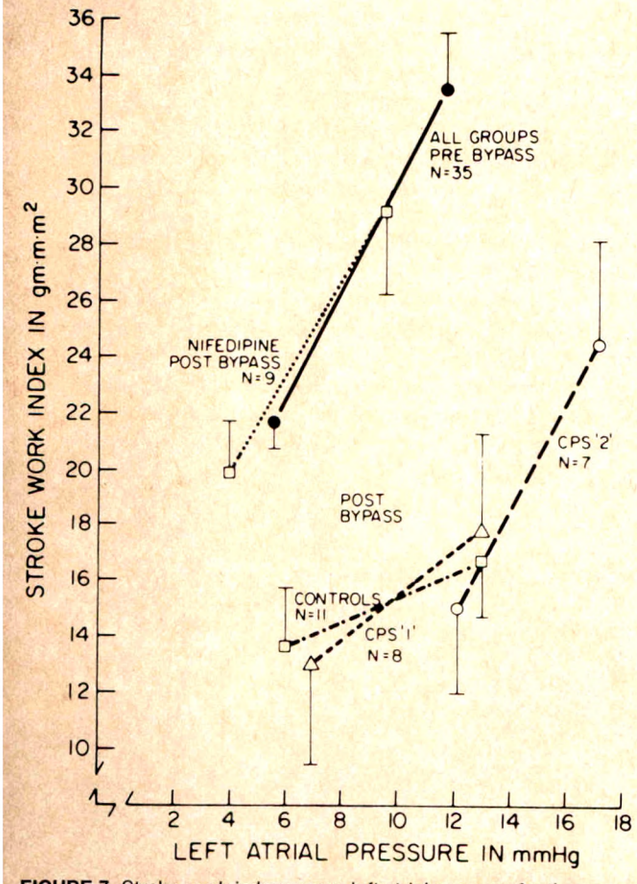

FIGURE 7. Stroke work index versus left atrial pressure for the same 4 groups of dogs as in Figures 1 and 2. Volume loading was achieved with 50 ml incremental infusions of whole blood to a total volume of 500 to 600 ml. Pre- and postischemia function curves are shown. Note that only the group treated with nifedipine-containing solutions achieved a normal work response to increases in preload. CPS = cardioplegic solutions. Reprinted with permission from *Ann Surg.*[39]

These data are summarized in Table VI and Figure 8. Although good protection was achieved with cardioplegic solution, significantly better hemodynamic results were achieved with the nifedipine-treated group. The data from pathology studies demonstrated no differences between the 2 groups.

Hypothermic experiments—3 hours of global ischemia: The experimental protocol was similar to that used for the 1- and 2-hour ischemic experiments. The dogs in this study were divided into 4 groups.

Cardioplegic solution: Ten dogs received seven 500-ml dosages of cardioplegic solutions initiated at the onset of ischemia and every 30 minutes thereafter during the 180 minutes of global ischemia.

Cardioplegic solution plus nifedipine: The 8 dogs in this group received seven 500-ml dosages of cardioplegic solutions containing nifedipine in concentrations of 200 to 300 μg/liter.

Intracellular-like cardioplegic solution: Six dogs received five 500-ml dosages of intracellular-like cardioplegic solution initiated at the onset of ischemia and every 45 minutes thereafter during the 180 minutes of global ischemia.

Intracellular-like cardioplegic solution plus nifedipine: The 6 dogs in this group received 5 dosages of solution containing nifedipine (200 to 400 μg/liter) at 45-minute intervals.

The preischemic and postischemic hemodynamic data are summarized in Tables VII, VIII and IX, and pertinent time-variable, LV function curves and degree of recovery of hemodynamic variables are illustrated in Figures 9 to 12. Before cannulation of the heart, all groups were statistically equivalent in 8 of the 10 variables listed in Table VII. For reasons unknown, the peak dP/dt and mean arterial pressures were increased in the 2 cardioplegic solution groups in comparison to the 2 intracellular-like cardioplegic solution groups before perfusion. Methodology was constant for all dogs in this study.

Two hours after termination of the 3.5- to 4-hour duration of cardiopulmonary bypass, most variables were as expected. In comparison to the prebypass values, there were small changes in dP/dt, peak LV pressure and heart rate, and significant changes in total peripheral resistance, mean arterial, left atrial and LVEDP. These alterations are characteristic of long hypothermic perfusion in dogs.

The 2 base solutions (cardioplegic solution and intracellular-like cardioplegic solution) differed little in resultant cardiac effects, although administered at different time increments (30 versus 45 minutes). The only 2 statistically significant differences were in dP/dt and total peripheral resistance (Table IV). There were no differences in SWI as a function of time (Fig. 9) or in the response to volume loading (Fig. 10).

The addition of nifedipine to cardioplegic solutions had no significant overall effect on postischemic cardiac performance in comparison to cardioplegic solutions

TABLE VI Comparison of 2-Hour Postbypass Values* for Bolus Aortic Root Injections During 2 Hours of Global Ischemia at 18°C

Variable	CPS (n = 8)	Nifedipine CPS (n = 8)	Statistical Comment
Heart rate (beats/min)	154 ± 10	161 ± 9	p = NS

MAP = mean arterial pressure. Other abbreviations as in Table V.

alone, although LVEDP and mean left atrial pressure were less than those in the cardioplegic solutions group. The marked depression of diastolic pressure in the cardioplegic solutions, cardioplegic solutions + nifedipine and intracellular-like cardioplegic solution groups resulted in low mean arterial pressure and low LV SWI, although cardiac output and stroke volumes were at preischemic levels.

The addition of nifedipine to the intracellular-like cardioplegic solution resulted in marked changes in one major variable, cardiac output (Fig. 11). Although the postischemic preload in the intracellular-like cardioplegic solution plus nifedipine group was similar to that in the cardioplegic solution plus nifedipine group, the lower heart rate and larger cardiac output yielded a large stroke volume. This, combined with the increased mean arterial pressure, resulted in a normal SWI (Fig. 9) that was approximately 2-fold greater than that observed in the other 3 groups after 3 hours of global ischemia. Additionally, the response to volume loading in the intracellular-like cardioplegic solution plus nifedipine group was in striking contrast to the postischemic performance of the other 3 groups. SWI increased by 65% with a 2-fold increase in left atrial pressure (Fig. 10). Thus, the composition of the cardioplegic solutions strongly influenced the effect of nifedipine.

One possible explanation for the observed differences is that the total sodium load presented to the heart with cardioplegic solutions was too large and the intra- and extracellular compartments became edematous to a degree not seen in the 1- and 2-hour hypothermic experiments. Conversely, it could be argued that a low sodium concentration in a cardioplegic solution augmented the action of nifedipine by maintaining lower extracellular concentrations of sodium ion.

Randomized Clinical Trial of a Calcium-Channel Blocker in Cardioplegic Solution

These studies led to a clinical trial of nifedipine in a cold, hyperkalemic, alkalotic, hyperosmotic cardioplegic

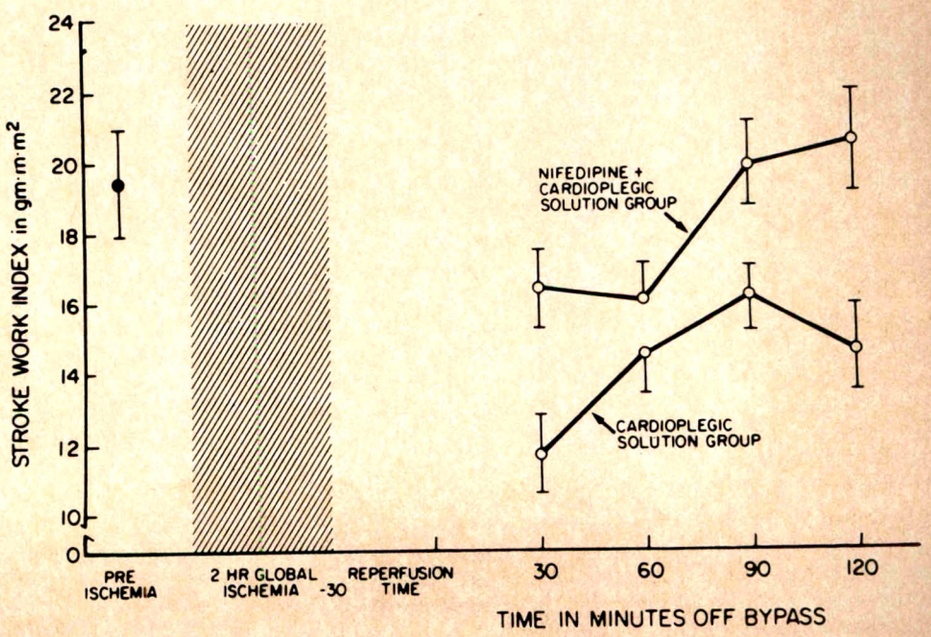

FIGURE 8. Stroke work index versus event and time after bypass for 2 groups of dogs given a clinical cardioplegic solution or the same solution with nifedipine added during 2 hours of global ischemia at an average myocardial temperature of 18°C. Heart rates and left atrial pressures were similar in both groups at the intervals after bypass. Reprinted with permission from *Ann Surg.*[39]

solution approved by the Food and Drug Administration and the Institutional Review Board of Washington University. The prospective randomized trial was sponsored by the National Heart, Lung, and Blood Institute, and patient enrollment began in May 1980.

Patient selection, classification and special studies: All patients entered into the protocol signed informed consent agreements before the initiation of special studies or use of the drug. Patients thought to be at increased surgical risk were selected for the study by the following criteria: (1) need for replacement of dysfunctioning prosthetic valve(s) with or without additional valve replacement in another position, (2) need for double or triple valve replacement, (3) need for prosthetic valve replacement because of significant coronary artery disease and valvular dysfunction and (4) presence of severe coronary artery disease with poor ventricular function with or without ventricular aneurysm. Patients expected to require these operations were classified by New York Heart Association (NYHA) (classes I to IV), Canadian angina classification (I to IV) and LV functional class.

The last classification was a composite that used (1) increases in LV diastolic volume index (class III, 30 to 50%; class IV, >50%), (2) LV ejection fraction, determined by planimetry of maximal systolic and diastolic phases of right anterior oblique ventriculography and the Dodge-Sandler calculation, equilibrated radionuclide ventriculography, or both, taking the least value, (3) presence of pulmonary hypertension as expressed by the mean pulmonary artery pressure (class III, 30 to 50 mm Hg; class IV, >50 mm Hg) and (4) the cardiac index (class III, 2 to 2.5; class IV, <2 liters min/m^2).

Patients enrolled in the protocol had 5 special serial studies performed throughout various phases of the hospital course. These were radionuclide ventriculography, isoenzyme creatine kinase (CK-MB) assays, Holter electrocardiographic (ECG) recordings, myocardial pyrophosphate scans and operative and postoperative hemodynamics.

Equilibrated radionuclide ventriculography was performed with technetium-99m from which both right and left global ventricular ejection fractions were calculated by computer as well as 8-segment wall motion analysis for each ventricle. These studies were performed 1 to 4 days preoperatively and 24 to 72 hours, 6 to 10 days and 6 to 9 weeks postoperatively.

Twenty-four-hour Holter ECG recordings were made preoperatively, for the first 72 hours postoperatively, and 1 and 6 to 9 weeks after operation using Avionics 2-channel recorders.

Myocardial isoenzyme CK-MB assays were performed by the glass bead method. Samples were obtained the evening before and the morning of operation, before and after the induction of anesthesia, at the time of incision and immediately before bypass. Subsequent samples were obtained at the termination of bypass, then every hour for 3 hours, then every 4 hours for 48 hours, then every 6 hours for 24 hours and finally every 12 hours for 48 hours. In all, 30 samples were taken, covering a minimal continuum of 132 hours. The concentration-time integral value was obtained by computer for the same time frame for all patients starting after perfusion.

Radionuclide myocardial pyrophosphate scans were performed 1 to 3 days preoperatively and 48 to 72 hours, 6 to 9 days and 6 to 9 weeks postoperatively with technetium-99m. Scans were graded from normal to 4+ uptake of isotope in terms of intensity and degree of localization noted.

Intraoperative and postoperative hemodynamic measurements were performed after induction, immediately before and at cessation of bypass, immediately before leaving the operating room, at 1 and 4 hours after arrival in the intensive care unit and every 4 hours

Measurement†	Treated (n = 39)	Not Treated (n = 35)
LV end-diastolic volume index (70 ± 20 ml/m^2)	103 ± 5.9	106 ± 9.2
Cardiac index (≥2.8 liters/min/m^2)	1.69 ± 0.09	1.73 ± 0.09
LV stroke work index (≥32 g·m·m^{-2})	20 ± 1.7	23 ± 1.9

* Data are shown as mean ± standard error of the mean.
† Normal values given in parentheses.
LV = left ventricular.

TABLE XI Preperfusion Hemodynamics

Variable	Control (n = 27)	Treated (n = 28)
Cardiac output (liters/min)	3,397 ± 182	3,198 ± 167
Cardiac index (liters/min/m^2)	1.8 ± 0.1	1.7 ± 0.1
Stroke volume (ml/beat)	43 ± 4	41 ± 3
Left ventricular stroke work index (g·m·m^{-2})	23 ± 2	20 ± 2
Right ventricular stroke work index (g·m·m^{-2})	3.9 ± 0.4	4.3 ± 0.4
Pulmonary vascular resistance (dynes s cm^{-5})	198 ± 23	166 ± 22
Total peripheral resistance (dynes s cm^{-5})	2,122 ± 161	1,988 ± 158

thereafter for 48 hours. Six to 9 weeks after operation, the principal investigator interviewed each patient, performed a physical examination and reviewed the current list of medications. Statistical analyses were performed using the Student unpaired and paired *t* test and chi-square test with the Yates correction for small numbers.

Randomization: Because nifedipine had never been used before in a cardioplegic solution in man, it was decided that before randomization, 10 patients would be given the drug to ascertain whether or not there were obvious untoward effects at the proposed dosage. Thereafter, assignment to cardioplegia or cardioplegia plus nifedipine was by a flip of a coin.

Operative conditions and cardioplegic administration: Myocardial temperatures were measured before and after infusion of cardioplegic solution and the resultant time-temperature course was integrated. This integral is more representative of the injury-susceptible interval than cross-clamp time alone, because myocardial injury is related to the duration of ischemia at a given temperature. The time-temperature integrals for the 2 groups were statistically similar for the cardioplegia and nifedipine groups, respectively (1,124 ± 129 versus 1,283 ± 83°C·minutes). The method of cardiopulmonary bypass was similar in all patients operated upon within the study period. A bubble oxygenator, roller pump, arterial line filter and hemodilution were used. The priming volume and composition were standardized, as were the anesthetic techniques.

The method used for administration of cardioplegic solution was identical for all the protocol patients. Each plastic bag containing the cardioplegic solution was evacuated of all air and covered with a brown plastic bag

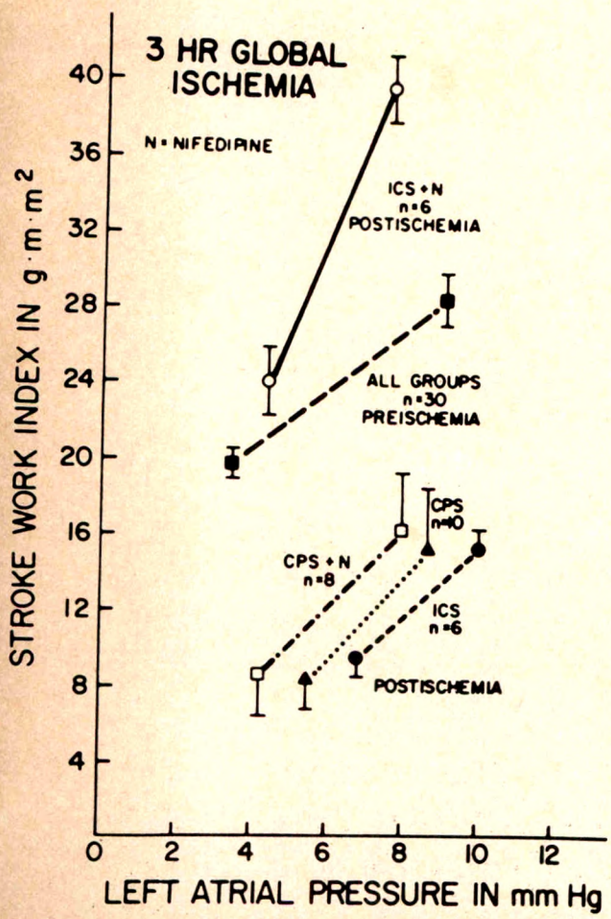

FIGURE 10. Stroke work index versus left atrial pressure before and after volume-loading tests with 500 ml of blood, before and 100 minutes after 3 hours of global ischemia under hypothermia (10° ± 2°C) and hypothermic (25°C) total cardiopulmonary bypass for all 4 groups. TABLE XII Postperfusion Hemodynamics

Variable	Control (n = 27)	Treated (n = 28)	Percent Change* Control (n = 27)	Percent Change* Treated (n = 28)
Cardiac output (liters/min)	4,101 ± 215	4,536 ± 116	+21	+42
Cardiac index (liters/min/m^2)	2.3 ± 0.2	2.5 ± 0.1	+28	+47
Stroke volume (ml/beat)	50 ± 3	56 ± 3	+16	+37
Left ventricular stroke work index (g·m·m^{-2})	27 ± 2	28 ± 2	+17	+40
Right ventricular stroke work index (g·m·m^{-2})	5.9 ± 0.9	6.2 ± 0.5	+51	+44
Pulmonary vascular resistance (dynes s cm^{-5})	250 ± 36	146 ± 16	+26	−12
Total peripheral resistance (dynes s cm^{-5})	1,727 ± 178	1,362 ± 87	−19	−31

* Percent change between data obtained before perfusion and those obtained after perfusion.

because of the sensitivity of nifedipine to light. Ingredients were added and the bags were maintained in the operating room on a bed of ice in a polystyrene container.

Each bag was connected to a 3/16 in (inner diameter) clear polyvinyl chloride tubing, which was connected to a DLP cannula (12 or 14 gauge) in the aortic root or to DeBakey coronary artery perfusion cannulas if the aorta was open. The bag was inserted into a pressurized infusion bag with the bladder pressure regulated at 80 to 150 mm Hg. Infusions were timed and the pressure was regulated to control the solution flow at 200 to 300 ml/min, which approximates normal human coronary artery flow of 80 ml/100 g heart weight/min. Flow calculations were performed by use of a spring scale calibrated in milliliters, which was accurate by our testing to ±4%. The solutions (500 to 1,000 ml) were infused every 30 ± 3 minutes.

The total amounts of drug and ion load to each heart were dependent on the ischemic interval. Potassium and lidocaine concentrations were decremental, as were sodium bicarbonate and tromethamine additions, because less of the latter 2 drugs was required to maintain an average pH of 7.8 at 37°C when the volumes of acidic solutions of the former 2 additives were decreased. The concentrations of potassium used per bag of cardioplegic solution were as follows: potassium chloride 25, 15, 10, 5 and 5 mEq/liter. Lidocaine concentrations were decreased in the cascade of 200, 100, 50, 25 and 0 mg/liter. Each bag was sampled for pH, carbon dioxide partial pressure, oxygen partial pressure, calculated bicarbonate radical and base excess by an ABL2 Radiometer analyzer (Radiometer A/S). Periodically, samples were sent to the Clinical Chemistry Laboratory for ionic, osmolar and drug analyses as a quality control measure. Nifedipine was added in a darkened room in constant amounts to each bag after other ingredients were added, to yield an average final concentration of 275 μg/liter.

Results: The preoperative assessment of the 39 treated and 35 nontreated patients was similar. The NYHA functional classes were 3.5 and 3.7 ± 0.1, angina class 1.5 and 1.8 ± 0.3 and LV functional class 3.2 and 3.4 ± 0.2, respectively. Distributions by age, sex, previous myocardial infarction, presence of atrial fibrillation and cardiomegaly, ejection fractions, ventricular ectopy rates, type of operation and surgeon were nearly identical. Comparative hemodynamic assessment before operation is shown in Table X. Further hemodynamic data obtained after induction of anesthesia but before opening of the chest are shown in Table XI and are similar. These data are for patients not requiring inotropic drugs or an intraaortic balloon pump; hence the number in each group is less than the total in the treated and nontreated groups.

The incidence of acute low cardiac output was 23% (8 of 35) in the nontreated group and 15% (6 of 39) in those receiving nifedipine in the cardioplegic solution (p = NS). One half of each group survived the interval of extreme low flow state, yielding short-term (1 to 72 hours postoperative) mortality rates of 11.5 and 7.5%, respectively (p = NS).

The primary effect of the addition of nifedipine was a short-lived hemodynamic one (Table XII). The percent change in cardiac index, stroke volume and LV stroke work in the treated group was nearly twice that observed in the group receiving cardioplegic solution only. Additionally, there were marked differences in the pulmonary and systemic vascular resistances.

A difference of nearly 40% between the 2 groups was present with respect to pulmonary vascular resistance. Patients treated with cardioplegic solution lacking nifedipine had an increase in this variable (26%), whereas those given cardioplegic solution with nifedipine had a small decrease of 12%. The decrease in total peripheral resistance was also greater in the nifedipine-treated group. There were no statistically significant differences

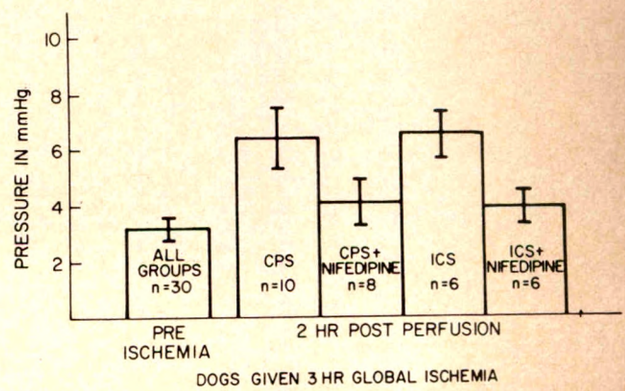

FIGURE 12. Preservation of left ventricular end-diastolic pressure in all groups subjected to 3 hours of hypothermic (10° ± 2°C) global myocardial ischemia under spaced multiple doses of 4 different myocardial protective solutions. Comparison of 120-minute postischemia values for each group to the preischemic values of all groups jointly. CPS = extracellular crystalloid cardioplegic solutions; ICS = intracellular-like, low sodium cardioplegic solutions. Reprinted with permission from *Surgery*.[38]

for heart rate, mean arterial pressure or right ventricular SWI between the 2 groups in the interval after perfusion.

Other studies: The technetium-99m pyrophosphate scans obtained were technically adequate in 34 patients treated with cardioplegic solution containing nifedipine and in 29 who had cardioplegic solution alone. In no patient receiving nifedipine did the blinded grading of the myocardial injury scan increase. Thirty of the 34 had no change and 4 had improvement. Of the 29 patients receiving cardioplegic solution alone, 20 had no change and 5 had improvement. However, 4 had a pattern of discrete injury postoperatively, which was not present on the preoperative examination. The CK-MB determinations, radionuclide ventriculograms and Holter recordings did not show any differences between the treated and control randomized groups.

Discussion

The concordant data obtained in the animal experiments reported here demonstrated a high degree of efficiency of the calcium-channel blocking agent nifedipine. The effects were dramatic and consistent, especially when the time interval of ischemia was prolonged either at normothermia or at low myocardial temperatures. The results of the randomized clinical trial were not as dramatic as those of the animal studies. The major findings were the difference in the hemodynamic status of the treated patients immediately after the cessation of cardiopulmonary bypass, and the difference in injury patterns as seen by myocardial scans. The benefit or lack thereof of continuation of nifedipine in the postoperative phase is unknown. No patient entered into this study was receiving a calcium-channel blocker before surgery and none received such an agent immediately after surgery.

The specific hypothesis of these studies was that nifedipine would decrease the incidence of acute low output syndrome and death. Although a trend toward this goal was shown, the use of the drug clearly did not eliminate this cause of death.

The hemodynamic assessments and myocardial scan data show that preservation was improved with nifedipine. Use of a calcium-blocking agent will not enhance biochemical energy stores; it will only retard the rate of degradation as shown by adenosine triphosphate studies during coronary artery bypass operation. Patients who are critically ill and have little reserve, therefore, remain at risk for myocardial power failure after global ischemia and reperfusion. Thus, use of nifedipine in cardioplegic solutions must be viewed as an adjunct and not a panacea for the prevention of myocardial injury in clinical surgery.

Calcium-Channel Blockers in the Treatment of Migraine

H. J. GELMERS, MD, PhD

According to classic theory, a migraine attack is initiated by cerebrovascular spasm followed by extracranial vasodilatation. Results of recent studies support this theory and suggest that cerebral blood flow during the initial phase of migraine symptoms is, in fact, decreased and this decrease probably leads to ischemia and hypoxia. Cellular hypoxia, in turn, can cause an increase in the flow of calcium from the extracellular fluid to the intracellular space, resulting in calcium overload and cellular dysfunction. Because calcium-channel blockers selectively inhibit the intracellular influx of calcium ions, investigators have begun evaluating the efficacy of these agents for migraine prophylaxis. Nimodipine, a calcium-channel blocker that exhibits selective effects on cerebral vessels, seems to offer protection against the cerebral ischemia and hypoxia presumed to be operative during migraine attacks. In a double-blind, placebo-controlled study, nimodipine decreased the frequency and duration of migraine attacks by at least half in 69% of patients treated with this agent. Comparable reductions in migraine frequency and duration were attained in 58, 51, 41 and 52% of patients treated with methysergide maleate, pizotifen, clonidine hydrochloride and propranolol, respectively. The piperazine derivative flunarizine also has calcium-channel blocking properties. This agent prevents vasospasm in cerebral arteries and protects against cerebral hypoxia. Results of double-blind studies of migraine prophylaxis with flunarizine demonstrate the beneficial effects of this agent, particularly in younger patients. Flunarizine proved to be superior to pizotifen in decreasing the severity of migraine attacks and comparable to pizotifen in decreasing their frequency. Thus, it appears that the prophylactic effects of calcium-channel blockers such as nimodipine and flunarizine are comparable to, if not better than, those achieved with some of the more frequently prescribed migraine preventives.

(Am J Cardiol 1985;55:139B–143B)

Several theories have been proposed to explain the mechanisms responsible for migraine attacks. Treatment selection often varies, depending on which theory a physician considers most plausible. Recently, investigators have suggested that diminished cerebral blood flow leading to hypoxia and intracellular calcium overload may be responsible for triggering migraine symptoms. Based on this hypothesis, calcium-channel blockers, which inhibit the intracellular flux of calcium, may offer a new prophylactic alternative for migraine sufferers.

Beginning with a basic description of migraine classification and pathophysiologic features, this report reviews the different theories of migraine origin. Major attention is focused on the potential role of hypoxia in migraine pathophysiologic features and the investigative findings that support the use of calcium-channel blockers for prevention of migraine attacks.

Types of Migraine

In clinical practice, the diagnosis of migraine is based on recurrent, severe, throbbing headaches, frequently unilateral in onset and usually associated with anorexia, nausea and vomiting. Some patients may have prodromal or concurrent neurologic symptoms and mood disturbances.[1] The nature and severity of associated symptoms determine whether the migraine is classified as *classic*, *common*, or *complicated*.[2]

Classic migraine begins with an aura of neurologic symptoms that are usually, but not always, visual. The most characteristic feature of the visual aura is the "fortification spectrum," which usually persists for about 20 minutes. The spectrum beings as a central or paracentral scotoma that enlarges in a semicircular pattern, forming a scintillating and serrated shape suggestive of a fort's embattlements. The flickering pattern becomes increasingly larger and more irregular as it approaches the periphery of the visual field and

then disappears. Visual symptoms are typically followed by a unilateral, throbbing headache that lasts for several hours and is accompanied by anorexia, nausea and vomiting. The patient usually recovers after a night's sleep.

Common migraine, which is what most migraine sufferers have, includes the throbbing headache and attendant gastrointestinal symptoms without the neurologic aura.

Complicated migraine is distinguished by neurologic features that are so severe they often obscure the diagnosis of migraine and may result in a persistent neurologic deficit.

Migraine Pathophysiologic Features

The classic theory of migraine development attributes the neurologic aura to intracerebral vasoconstriction, which induces the extracranial vasodilatation responsible for the severe headache. During the 1930s and 1940s, Wolff[3] wrote a series of reports supporting and developing this theory. One of his more noteworthy findings was the disappearance of the visual aura in patients who inhaled amyl nitrite, a well-known vasodilator. This discovery was considered incontrovertible evidence that the aura was caused by vasoconstriction. Their additional findings favoring vasodilatation as the cause of the headache included the throbbing, pulsatile nature of the headache; the associated dilatation and tenderness of the superficial temporal artery; and the disappearance of symptoms after compression of the internal carotid artery or treatment with the vasoconstrictor ergotamine.

Differing theories have evolved to explained the events that characterize a migraine attack. Two of the more widely recognized are described as follows.

Humoral model: Wolff suggested the possibility that humoral control of cranial vessels is defective during a migraine attack. He and his associates[4] isolated what they called "headache stuff," which was subsequently identified as substances that accumulate around dilated cerebral arteries and sensitize them to pain. A number of such substances have been identified as possible contributors to migraine symptoms. These include amines (serotonin, catecholamines, histamine and tyramine), polypeptides (bradykinin and angiotensin), prostaglandins and adenosine monophosphate.

The humoral theory of migraine origin is supported by a cyclic sequence of events detected in patients who have *classic* migraine attacks. The cycle begins with an increase in the plasma norepinephrine concentration during the prodromal, or neurologic, phase.[5] The increased norepinephrine concentration serves to exacerbate the already increased platelet aggregation present in many migraine patients.[6] The release of serotonin and adenosine diphosphate from the aggregated platelets perpetuates the cycle by causing an even greater increase in platelet aggregation.

Serotonin is capable of exerting complex vascular effects that can lead to arterial constriction and capillary dilatation[7]; serotonin depletion elicits an opposite set of reactions.[8] Serotonin also increases the permeability of the blood-brain barrier and thereby promotes its own entry into the brain.[9] In migraine patients, serotonin seems to facilitate the intracranial arterial vasoconstriction leading to neurologic symptoms, which are usually visual. In time, the serotonin concentration decreases, and the tonic constricting effect subsides.

The decrease in serotonin concentration may contribute to the extracranial vasodilatation and associated headache, but it is probably not the sole cause of the headache. The release of neurokinins from aggregated platelets and mast cells is thought to sensitize pain receptors in the walls of extracranial vessels,[10] which would explain the tenderness in the scalp and neck vessels often associated with an acute migraine attack.

Although the sequence of aforementioned events described seems to be well accepted, more recently acquired data seriously challenge this explanation of migraine pathophysiologic make-up and suggest that the "hypoxia model" described as follows may be a more likely scenario.

Hypoxia model: Results of blood flow studies conducted during the late 1960s and early 1970s[11,12] supported the classic theory of vasoconstriction followed by vasodilatation; cerebral blood flow was reported to decrease during the aura, or neurologic phase, and to increase during the headache phase. However, within the past few years, preliminary findings obtained with more direct methods for measuring cerebral blood flow indicate that a different sequence of events may occur.

Olesen et al[13] reported the rather startling finding that oligemia, rather than hyperemia, characterized the headache phase of classic migraine. Even in several patients who had focal hyperemia as the initial migraine event, there was no evidence of hyperperfusion during the headache phase. The oligemia began in the occipitoparietal region and spread forward, gradually encompassing the entire hemisphere. Because the spread of oligemia was not in accordance with the territories supplied by the larger cerebral arteries, the investigators thought it was unlikely that the migraine was caused by spasm of these vessels. These findings led to the suggestion that the vascular changes associated with migraine attack may be secondary to a primary event in the cerebral parenchyma.

Cerebral blood flow studies in patients with *common* migraine have yielded conflicting results. Although some investigators found no alterations in blood flow, either focal or global,[14] others reported changes similar to those observed by Olesen et al in patients who suffer from *classic* migraine.[15]

The spread of the migrainous visual aura (the fortification spectrum) during the neurologic phase resembles the progression of Leao's "spreading cortical depression," an inhibitory wave that is preceded by a phase of short-lived neuronal activation.[16] This resemblance has led to the suggestion that the migrainous visual aura and the spreading cortical depression may be one and the same. Animal experiments have shown that spreading cortical depression can be chemically triggered. For example, the application of potassium chloride to the cerebral cortex has been shown to elicit

this depression.[17] It is therefore conceivable that localized cerebral hypoxia initiates the spreading cortical depression typical of migraine attacks by inducing focal increases in cerebral extracellular potassium levels.

As mentioned in the discussion of the humoral model, norepinephrine and therefore the sympathetic nervous system, may contribute to the genesis of a migraine attack. Migraine sufferers seem to have a persistent degree of vasoconstriction during headache-free intervals. This finding has been interpreted as a sign of excessive sympathetic tone. An adrenergic system has been demonstrated to be diffusely present in the pontine and medullary regions of the brain, and also in a well-localized area, the locus ceruleus.[18] From these areas, the system projects anteriorly, terminating both synaptically and as free boutons. There is evidence indicating that the effects of the central sympathetic system on cerebral blood flow and vascular permeability are similar to the effects of the peripheral sympathetic system on the peripheral vasculature.[19] Hence, it is possible that the peripheral humoral changes noted during a migraine attack merely reflect critical alterations in neurohumoral activity.

In the context of migraine-associated hemodynamic changes, it is important to mention that a migraine attack is often preceded by a state of arousal. Arousal can cause focal increases in cerebral metabolism, increasing local tissue requirements for oxygen. As the need for oxygen increases, vessels in the surrounding area dilate to ensure that blood flow is sufficient to satisfy this need. (It should also be noted that a general state of arousal is usually associated with an increase in catecholamine secretion, which can lead to the changes described previously.)

It is tempting to speculate that any increase in sympathetic tone involving cerebral circulation decreases the vasodilatory response to local tissue acidosis as well as to hypercapnia or hypoxia.[20] Therefore, it is possible that excessive sympathetic tone prevents cerebral vessels from dilating sufficiently to match the increased requirement for oxygen. Such an uncoupling between supply and demand can lead to cerebral hypoxia, the event believed to trigger a migraine attack.

The cerebral hypoxia model of migraine origin derives primarily from studies of regional cerebral blood flow. The remarkable similarities between cerebral hypoxia and "spreading cortical depression" lead one to assume that focal brain hypoxia occurs early in the migraine attack, giving rise to the "spreading cortical depression." According to this model, the cortical depression would be the result rather than the cause of brain hypoxia. The neuronal activation that precedes the depression wave would temporarily increase oxygen demand and, thus, aggravate the early hypoxia.

There is more direct evidence that hypoxia occurs during a migraine attack. Such evidence includes biochemical alterations typical of brain hypoxia[21,22] and, in severe cases of migraine, organic brain changes, ranges from cerebral edema to permanent ischemic lesions.[8,23]

The hypoxia model suggests that cerebral hypoxia occurs in every attack of migraine, but whether the hypoxia, along with the associated spreading wave of cortical depression, manifests as neurovisual phenomena depends on the severity of the hypoxia and its location in the brain. Whether an episode of hypoxia will lead to a full-blown migraine attack depends largely on the nature of the ensuing whirlpool of biochemical and vascular changes.

Treatment

Migraine patients' conditions can be managed either by treating symptoms once an attack is underway (symptomatic therapy) or by preventing the attack altogether (prophylactic therapy). However, symptomatic treatment is usually not as effective as preventive therapy. Pharmacologic agents that will terminate an attack include various ergotamine derivatives combined with caffeine (which acts synergistically with the ergot alkaloids), antispasmodics, sedatives and antiemetics.

The various models of migraine origin can provide clues for developing additional therapeutic approaches for interrupting or preventing the pathophysiologic sequence of events that leads to a migraine attack. The humoral model, although based on concepts that remain to be conclusively substantiated, suggests a wide range of symptomatic and prophylactic treatment options. Because the placebo response in migraine trials ranges from 20 to 40%, a response rate of at least 50% is considered necessary to substantiate therapeutic effect.[24] Regimens based on the humoral model have been described in detail by Friedman,[25] and will not be reviewed here. The remainder of this discussion focuses on treatments founded on the hypoxia model of migraine origin.

If, as many investigators suspect, a hypoxic focus is essential to the onset of a migraine attack, it is logical to assume that the attack will not occur if hypoxia can be prevented. Therefore, drugs that protect the brain from hypoxia may be useful in preventing migraine attacks. Calcium-channel blockers are an obvious choice. In several tissues, cellular hypoxia induces excessive calcium influx across the cell membrane, leading to cellular dysfunction. Using calcium-channel blocker therapy to inhibit this massive shift in calcium concentration appears to prevent cellular dysfunction and improve cerebral tissue perfusion.

Nimodipine treatment: Nimodipine, a dihydropyridine derivative, is a new calcium-channel blocker that has been shown to dilate cerebral vessels[26] and to protect against cerebral ischemia and hypoxia.[27] It is the most potent, and possibly the most selective, cerebral vasodilator of the calcium-channel blockers currently being studied. Its therapeutic profile, therefore, seems ideally suited to migraine prophylaxis.

To date, 2 clinical studies have examined the efficacy of nimodipine in the prevention of migraine symptoms. In a double-blind, placebo-controlled evaluation of prophylactic treatment with this agent, it was found that nimodipine significantly decreased the frequency of migraine attacks.[28] In a similar study, 69% of patients treated with nimodipine had ≥50% decrease in the

TABLE I Response to Migraine Prophylaxis*

Agent	Patients With ≥50% Improvement (%)
Methysergide maleate	58.3
Pizotifen	50.9
Clonidine hydrochloride	40.9
Propranolol	51.6
Amitriptyline	72.0
Nimodipine	69.0

* Adapted from Cough JR, Hassanein RS. Amitriptyline in migraine prophylaxis. Arch Neurol 1979;36:695–699.

frequency and duration of migraine attacks (Fig. 1); however, the severity of the headache once it occurred was reduced to a lesser extent.[29] The level of response to nimodipine was comparable to or better than that obtained with other migraine prophylactic agents (Table I).

Adverse effects noted in associated with nimodipine therapy were minimal. During the initial days of treatment, a few patients reported mild abdominal discomfort, which was attributed to obstipation resulting from relaxation of intestinal smooth muscle. No episodes of hypotension or reflex tachycardia were observed.

Flunarizine treatment: Flunarizine, a difluorated piperazine derivative, is another calcium-channel blocker that has been used in clinical investigations of migraine prophylaxis. This compound has been shown to prevent vasospasm in cerebral arteries;[30] consequently, it was suggested that flunarizine might be effective in preventing ischemia and in protecting against ischemia-induced cellular dysfunction by preventing intracellular calcium overload.[31,32]

Three double-blind investigations have evaluated the efficacy of flunarizine in migraine prophylaxis. Study populations were limited to patients with a diagnosis of *classic* or *common* migraine. One study showed that flunarizine decreased the frequency but not the severity of migraine attacks in younger patients.[33] Another showed that the effects of flunarizine were largely comparable to those of pizotifen.[34] (Pizotifen, a serotonin antagonist, was the first agent considered safe for prevention of migraine and remains the standard against which all migraine prophylactic agents are compared.) Although the 2 agents produced similar decreases in the frequency of attacks, flunarizine proved to be superior in decreasing the severity of the attacks. The third study compared the effects of flunarizine with those of cinnirazine, a piperazine derivative with some calcium antagonistic properties. Results of this study indicated that the drugs were comparable in their ability to decrease the frequency and duration of migraine attacks.[35]

Daytime sedation was the most frequent adverse effect noted in association with flunarizine therapy. However, the sedative effect was not considered sufficiently severe to impede long-term treatment.

In summary, currently available clinical and research findings are compatible with the hypothesis that cerebral hypoxia induced by hypoperfusion is causally related to migraine onset. Identification of this pathophysiologic mechanism, together with the recognition that the hypoperfusion might be related to vasospasm, led to the investigative use of calcium-channel blockers for preventive therapy in patients with migraine. Results of clinical studies suggest that the prophylactic effects of these agents are comparable to, if not better than, those achieved with more standard migraine preventive agents.

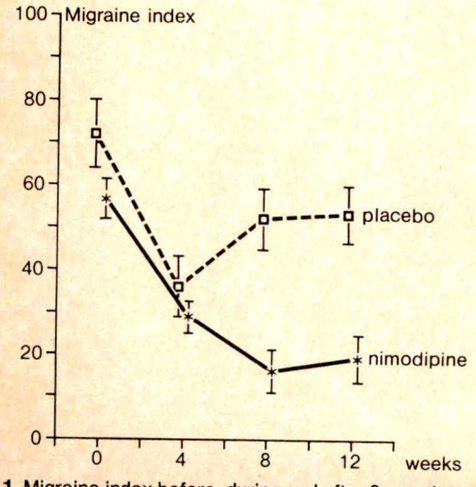

FIGURE 1. Migraine index before, during and after 3-month treatment with nimodipine, 120 mg daily (n = 28), or placebo (n = 22). Migraine index is composite representation of number, severity and duration of migraine attacks. At end of 3 months, migraine index for nimodipine-treated patients was significantly better ($p < 0.01$) than that for control subjects.[29]

Calcium-Channel Blockers: Effects on Cerebral Blood Flow and Potential Uses for Acute Stroke

H. J. GELMERS, MD, PhD

Current research suggests that ischemia induces a massive shift of calcium from the extracellular fluid to the intracellular space. This is associated with a precipitous decrease in the concentration of adenosine triphosphate, the energy source required to drive the ion pumps of the calcium channels that maintain intracellular calcium homeostasis. The result is a further increase in free intracellular calcium, leading to calcium overload and thus to cell catabolism and cell necrosis. Treatment with calcium-channel blockers may therefore offer a new approach to arresting and, possibly, preventing destruction of cerebral tissue in stroke victims. Animal studies using nimodipine, a calcium antagonist with marked vasodilator effects, have shown that this agent prevents both spasm of the isolated rabbit basilar artery, produced either by depolarization or by receptor stimulation, and postischemic impairment of cerebral blood flow (CBF), which may be a major contributor to neuronal damage. In patients with acute ischemic stroke, intravenous nimodipine therapy caused a dose-dependent increase in hemispheric CBF. These data prompted us to conduct a prospective, single-blind, randomized trial of 60 patients to determine whether nimodipine treatment would reduce neurologic deficits in patients with acute ischemic stroke. The 29 treated patients were given standard dextran therapy supplemented with daily 120 mg doses of nimodipine, and the 31 control subjects received dextran therapy alone. Mathew scale neurologic scores indicated decreased consciousness and impaired cerebral function in both treated and control groups; however, cerebral deficits were significantly smaller in patients who received nimodipine. Adverse effects were minimal and clinically insignificant. These preliminary results suggest that calcium shifts can greatly influence the extent of cerebral damage in stroke victims and calcium antagonists may be useful in treating such patients.

(Am J Cardiol 1985;55:144B–148B)

Despite major advancements in our understanding of the pathophysiologic features of the cerebral circulation, very little progress has been made in our ability to arrest or prevent the functional impairment that often follows acute ischemic stroke. As we continue to learn about the mechanisms that control cerebral blood flow (CBF), we realize that the extent of irreversible cerebral damage is governed by both the duration of ischemia and the rate of blood flow within the ischemic area. In addition, there is evidence suggesting that ischemia-induced shifts of calcium from extracellular to intracellular sites also influence the degree of cerebral functional impairment.

As a result of these findings, physicians are beginning to consider new pharmacologic approaches to managing stroke victims. Most recently, investigations have focused on the potential of calcium-channel blockers to minimize neurologic deficits by altering CBF in ischemic regions. The discussion that follows describes research that culminated in the investigative use of the calcium antagonist nimodipine to treat stroke victims.

Cerebral Blood Flow and Neurologic Function

Animal studies examining the relation between CBF and neurologic function have led to the definition of flow thresholds that correlate with the severity of cerebral dysfunction. Results of these studies indicate that when the perfusion rate decreases below a certain threshold (about 20 ml/min/100 g), cerebral function becomes impaired.[1–4] A further sustained decrease in CBF to below the critical limit of 8 to 10 ml/min/100 g can lead to irreversible functional impairment. The upper level is known as the "flow threshold for failure of neuronal function,"[5] and the lower level is referred

to as the "flow threshold of membrane failure."[6] When the perfusion rate within an ischemic area ranges between these 2 thresholds, the condition is known as "ischemic penumbra."[5]

Principles of Cerebral Blood Flow Measurements

The development of reliable techniques for measuring CBF has contributed substantially to our knowledge of the mechanisms governing normal CBF and those responsible for the flow derangements that occur in patients with acute ischemic stroke. All current methods for assessing CBF can be traced to Kety and Schmidt,[7] who, in 1945, described the use of an indicator injection technique, based on the Fick principle.

In 1961, Lassen and Ingvar[8] reported a significant advance in CBF monitoring. Their procedure is founded on the assumption that the perfusion rate within a particular tissue can be determined from the rate at which a freely diffusible and inert indicator is cleared by that tissue. If, for example, a gamma-emitting isotope is used as the indicator, the clearance rate of this isotope can be recorded noninvasively by scintillation detectors placed on the patient's head. From the clearance rate, the physician can obtain a clearance curve, and, from the clearance curve, the CBF can be calculated using 1 of several methods. Recording the isotope clearance from many fairly small areas of the brain by means of multiple scintillation detectors allows determination of regional cerebral blood flow (rCBF). The principles and techniques of rCBF calculation have been described in depth by several investigators[9–11] and will not be reviewed here.

Because neurologically healthy persons rarely undergo CBF evaluations, true normal rCBF values are not readily obtainable. Nevertheless, most study populations include at least a few patients who are without evidence of organic brain disease. Normal rCBF values derived from such patients typically vary from 45 to 60 ml/min/100 g, depending upon the measuring technique and method of CBF calculation used.[9] Normal rCBF is nonhomogeneous under resting conditions. A normal rCBF pattern obtained at rest in a silent room with the patient's eyes closed is characterized by high flow rates in the precentral, premotor and frontal regions and by low flow rates in the temporal regions.[12]

The physiologic mechanisms that control rCBF are complex, but, for the purposes of this discussion, can be described as a series of interdependent factors. CBF is ultimately regulated by the metabolic activity of neuronal tissue. An increase in neuronal metabolism augments carbon dioxide (CO_2) production. The increase in CO_2 concentration decreases extracellular pH and causes cerebral vasodilation leading to increased CBF. When neuronal activity diminishes, an opposite scenario occurs: CO_2 production diminishes causing a decrease in cerebral vasodilation and CBF.

Hemodynamic Disorders

In most patients with acute ischemic stroke, the involved hemisphere shows decreased perfusion, which is sometimes attended by a transient decrease in blood flow in the contralateral hemisphere. This remote effect has been attributed to a transneuronally mediated depression of metabolism.[13,14]

Within the ischemic hemisphere, the perfusion rate can vary from region to region. Focal areas of decreased CBF tend to occur within the infarcted area whereas hyperemic regions can sometimes be found at the periphery of the infarct.[15] The presence of hyperemic areas is described as the "luxury perfusion syndrome" and has been attributed to local metabolic acidosis.[16]

Derangements in CBF autoregulation have been observed in stroke patients. Autoregulation of CBF is defined as the inherent ability of the cerebral vasculature to maintain a constant blood flow over a wide area of cerebral perfusion pressure. The upper and lower limits of the mean arterial blood pressure required to maintain CBF within a normal range are 50 and 160 mm Hg, respectively.[17,18] After stroke, autoregulation is often lost, presumably because the vessels supplying the ischemic region are maximally dilated. As a result, CBF becomes pressure-dependent at all levels of perfusion pressure. (Some patients with global loss of autoregulation have a focal parodoxical response to an increase in blood pressure.[19] The increase in blood pressure is thought to increase intracranial pressure, causing increased cerebrovascular resistance in the infarcted area and, consequently, a decrease in rCBF. Normal autoregulatory function may return within days or weeks of the ischemic episode.) In addition, the normal response of cerebral tissue to CO_2 may be decreased or absent, and paradoxical reactions may occur. These paradoxical reactions, characterized by a decrease in CBF in response to CO_2, have been attributed to the following processes. Ischemic areas probably lose their responsiveness to CO_2 as a result of accumulated acid metabolites, mainly lactic acid, whereas the more normal surrounding areas remain reactive to CO_2. In the presence of hypercarbia, the vessels in the periischemic area dilate, creating a zone of decreased cerebrovascular resistance and decreased perfusion pressure surrounding the ischemic region. The decrease in perfusion pressure diminishes the blood flow within the ischemic area. This set of conditions is often described as the "intracerebral steal syndrome."[20]

Role of Calcium in Ischemic Cell Damage

Recently, the importance of calcium in ischemic cell damage has been the focus of considerable discussion and investigation. Schanne et al[21] were among the first to support the hypothesis that calcium plays a major role in the pathophysiologic features of cell injury. They showed that a wide range of membrane-active toxins can cause toxic cell death only in the presence of a normal extracellular calcium concentration. When the extracellular calcium concentration was decreased to the level of a normal intracellular calcium concentration, the toxins had little effect.

During cerebral ischemia, there is a massive shift of calcium from the extracellular fluid into the intracellular space.[22,23] The increase in intracellular calcium is accompanied by a precipitous decrease in the concentration of adenosine triphosphate, the energy source required to drive the ion pumps within the calcium

channel that maintain intracellular calcium homeostasis. This defect augments the increased intracellular calcium concentration, producing calcium overload.

Calcium overload exerts many detrimental effects that can lead to cell catabolism and, ultimately, to cell necrosis. For example, calcium activates the enzyme phospholipase A_2, which releases free fatty acids (FFAs) from membranes.[24] Consequently, anoxic-ischemic neuronal injury is characterized by a large and rapid increase in neuronal FFA content, especially arachidonic acid content. Arachidonic acid can initiate the important sequence of biochemical events that leads to the production of eicosanoids, such as prostaglandins, thromboxanes and leukotrienes.[25] Specific compounds within each of these groups are capable of causing cell damage. Increased FFA levels in neurons also trigger the production of free radicals.[26] Although the role of these oxidative radicals in neuronal injury remains controversial,[27] the potential entropic threat posed by their ability to initiate deleterious biochemical reactions cannot be ignored.

Calcium overload also appears to be related, directly or indirectly, to the delayed, inadequate reperfusion that typically follows anoxia-ischemia. Such hypoperfusion has been associated with myofibrillar contracture and increased vascular resistance.[28]

When considered together, these findings are compatible with the thesis that increased intracellular calcium concentrations play a pivotal role in the events leading to neuronal death after anoxia-ischemia.[24,29] If, indeed, the sequence of events depicted in Figure 1 is valid, interventions that break the cascade at 1 or more points may result in the salvage of cerebral tissue. Using calcium-channel blockers to decrease the intracellular influx of calcium is 1 such intervention; consequently, studies designed to assess the value of calcium-channel blockers in treating patients with acute ischemic stroke seem justified.

Pharmacology

Calcium-channel blockers are a rather nonhomogenous group of drugs, containing derivatives of papaverine, dihydropyridine and piperazine. These drugs have widely differing structures, potencies and tissue-dependent specificites. Their 1 common property is the ability to interfere with an action-potential–induced transmembrane movement of calcium.

The papaverine derivatives, such as verapamil and D-600, have been shown to block contractions of the surgically exposed cat basilar artery. Flunarizine, a piperazine derivative, appears to block contractions in both basilar and internal carotid arteries.[30]

The most potent vasodilators among the calcium antagonists are the 1.4-dihydropyridine substitutes nifedipine and nimodipine, and nimodipine is the more powerful of the 2. These compounds have been shown to block contractions in the canine basilar artery at concentrations that are 10,000 times less than the concentrations of papaverine required to block contractions in the feline basilar artery.[2]

The activity of these agents appears to be tissue-, organ- and, in some instances, species-specific. When administered in clinically relevant doses, nifedipine was more effective in blocking the calcium channels in smooth muscle than in cardiac muscle, and appeared to have little if any effect on pacemaker activity and atrioventricular nodal conduction.[31] Results of other studies indicate that agonist-induced contractions of the basilar arteries in dogs[32] and rabbits[33] can be inhibited by nimodipine, whereas contractions of femoral arteries in these animals are affected to a lesser degree. The differences in tissue specificity have been attributed to variations in the types of calcium channels present in different tissue types, whereas their organ- and, possibly, species-specificity are thought to reflect variations in the distribution of these channels.

Animal models of calcium-channel blocker therapy in ischemia: One well-studied model of ischemic brain damage, the rat preparation by Levine,[34] has recently been used in pharmacologic investigations of calcium-channel blockers. In this model, cell

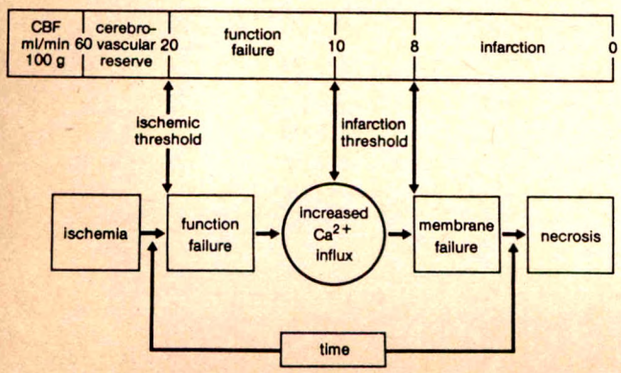

FIGURE 1. The ischemic cascade. Values are approximations obtained from experimental data. CBF = cerebral blood flow.

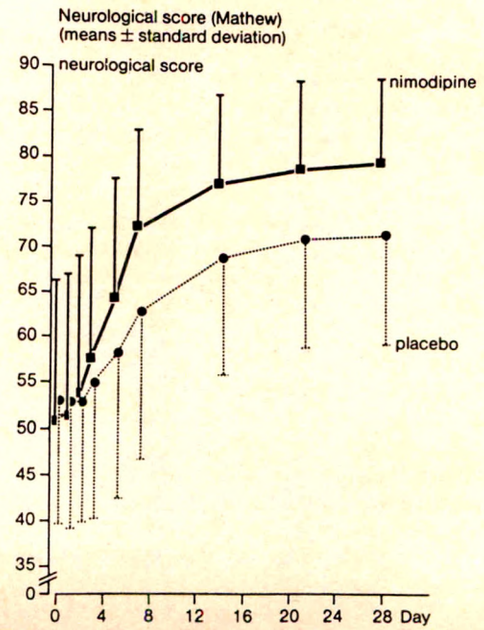

FIGURE 2. Mathew scale neurologic scores for ischemic stroke patients treated with nimodipine (n = 29) or placebo (n = 31).

changes typical of ischemia are produced by intermittently exposing rats to a pure nitrogen environment for several 1-minute intervals during a 40-minute period. Artificial respiration is administered after each interval of oxygen deprivation. Using this model, investigators sought to determine whether flunarizine offers pharmacologic protection against ischemic cell changes.[33] Flunarizine-treated rats had only moderate ischemic cell damage in limited areas, lending support to the hypothesis that ischemic cell necrosis is the result of calcium overload. However, these findings remain to be corroborated by clinical studies.

Animal studies of dihydropyridines have yielded findings similar to those obtained with flunarizine. Treatment with nimodipine was found to prevent impaired cerebral reperfusion after a 7-minute interval of total cerebral ischemia.[35] In a separate study, investigators found that the progressive deterioration evident on electroencephalograms recorded during the later stages of the ischemic and postischemic phases was absent in animals premedicated with nimodipine.[36]

Results of nimodipine treatment in baboons were inconsistent; the drug either increased CBF without affecting cerebral metabolism or it decreased blood flow.[37] The disparity between these and other animal findings is probably traceable to differences in study design and methods because the effect of nimodipine on CBF varied with the type of animal preparation used.

Clinical findings: CBF measurements in volunteers and stroke patients suggest a small overall increase in CBF after nimodipine treatment, with a redistribution of blood flow within the infarcted hemisphere.[38,39] These findings are in agreement with those indicating that stroke patients have increased blood flow in ischemic areas and decreased blood flow in unaffected cerebral areas, whereas hemispheric blood flow remains unaltered.[40]

Nimodipine Clinical Trial

To date, results of only 1 clinical trial evaluating the effects of calcium-channel blocker therapy on the neurologic deficits resulting from acute ischemic stroke are available.[41] Designed as a 1-center, randomized, single-blind, pilot investigation, the study included 60 patients with acute ischemic stroke. Diagnosis was confirmed by a complete neurologic work-up, which included electroencephalogram, lumbar puncture, radioisotope brain scans, and computerized axial tomography scan. All patients were entered into the study within 24 hours of the onset of neurologic symptoms.

Of the 60 patients, 29 were selected for nimodipine treatment, and the remaining 31 were designated as control. All 60 patients received a standard regimen of 10% depolymerized dextran for 5 days. The 29 patients randomized to calcium-channel blocker therapy received additional treatment for 28 days with 120 mg/day of nimodipine administered either orally or, in the case of patients with dysphagia, by nasogastric tube. Heparin therapy (10,000 IU divided between 2 doses) was given subcutaneously for prevention of deep-vein thrombosis. Digitalis, antihypertensives and antibiotics were administered as required, but treatment with vasodilators, steroids and hyperosmolar agents was withheld.

Treated and control groups received comparable supportive care from nurses, physical, speech and occupational therapists, and other members of the hospital staff. Differences between the 2 groups in patient characteristics (for example, mean age, sex, stroke type and risk factors) were not statistically significant.

Therapeutic efficacy was assessed using the Mathew scale for neurologic scoring.[40,42] As shown in Figure 2, pretreatment scores for the 2 groups were similar; however, on Day 8 of nimodipine treatment, the neurologic scores for treated patients began to differ from those for control subjects. This disparity persisted throughout the remainder of the 4-week study, indicating greater recovery of neurologic function in the nimodipine-treated patients compared with those who received dextran therapy alone ($p < 0.0001$).

During the period of observation, both treated and control groups showed minimal decreases in systolic blood pressure; however, in no patient did the decrease herald a deterioration in clinical condition. The differences between the blood pressure readings for the 2 groups were not statistically significant. Mean heart rate increased initially with standard therapy, but decreased during nimodipine treatment. No other clinically relevant adverse effects were noted in either study population.

In summary, animal and clinical findings accrued to date support the theory that calcium influx into cerebral cells during ischemia contributes to cell death. Animal data indicating that calcium antagonists protect neuronal cells from ischemia, together with clinical evidence attesting to improved neurologic function after nimodipine treatment, suggest that calcium-channel blockers offer promise in the management of patients with acute ischemic stroke. It should be noted, however, that the results of 1 single-blind study cannot be considered conclusive and must be confirmed by further investigation. To fulfill this need, double-blind studies of nimodipine therapy in stroke victims are currently underway.

Role of Calcium Antagonists in Cerebral Arterial Spasm

GEORGE S. ALLEN, MD, PhD

Spasm of the large cerebral arteries at the base of the brain causes delayed ischemic neurologic deficits in approximately 30% of patients after a subarachnoid hemorrhage from an intracranial aneurysm. In vitro chamber studies have shown that both dog and human large cerebral artery segments contract to a variety of vasoactive agents, and the dog and human segments are remarkedly similar in their responses. The source of calcium necessary to initiate contraction was found to be extracellular for large cerebral arteries. In contrast, systemic arteries such as the femoral artery use a bound intracellular pool of calcium for contraction. The calcium antagonists nifedipine and nimodipine were found to selectively inhibit the contractions of large cerebral arteries but not the femoral artery. In vivo experiments demonstrated that both nifedipine and nimodipine, given sublingually, would prevent and reverse cerebral arterial spasm in the dog after a subarachnoid hemorrhage. Nimodipine was found to be more potent, both in the chamber and in the live dog experiments. Nimodipine significantly decreased the occurrence of severe neurologic deficits from spasm alone in a multi-institutional, prospective, double-blind, randomized, placebo-controlled trial. **(Am J Cardiol 1985;55:149B–153B)**

The patient who survives a subarachnoid hemorrhage from an intracranial aneurysm remains at risk during the next 3 weeks because of recurrent hemorrhage and cerebral arterial spasm. Recurrent hemorrhage is effectively treated by clipping the aneurysm. Cerebral arterial spasm is focal or diffuse narrowing of ≥1 of the large arteries at the base of the brain. Such spasm is rarely seen on angiograms taken within the first 96 hours after the hemorrhage. In contrast, it is frequently seen from 4 to 21 days after the hemorrhage. It is now well accepted that delayed (several days after the initial hemorrhage) ischemic neurologic deficits are caused by spasm. The time course of the onset of the neurologic deficits coincides with the time course of spasm seen on angiograms (4 to 21 days after the hemorrhage). The peak incidence for the onset of a neurologic deficit is the ninth day after hemorrhage. The incidence of such delayed neurologic deficits is highest in the group of patients whose initial computerized axial tomography (CAT) scans show large amounts of blood in the basal subarachnoid cisterns. Neurologic deficits are very infrequent in those patients whose initial CAT scans fail to disclose any blood in the basal cisterns. The exact cause of spasm and the chain of events leading to the ischemic neurologic deficit have not been firmly established. A reasonable working hypothesis is that one or more vasoactive substances contained in the blood clots in the basal cisterns interact with the cerebral arteries to cause severe constriction. After some period of severe constriction, there are morphologic changes that take place in the wall of the cerebral arteries, such as swelling and necrosis of the smooth muscle cells. Such morphologic changes in the arteries may cause them to remain narrowed without the continued presence of vasoactive substances. The net result is ischemia to the area of the brain supplied by the vessel in spasm. Approximately 30% of all patients with a subarachnoid hemorrhage will have delayed neurologic deficits from spasm, and half of these patients will either die or be left with severe neurologic deficits.

If the initial event in the development of cerebral arterial spasm is the contraction of the smooth muscle cells in large cerebral arteries, then a drug that inhibits these contractions should prevent both spasm and neurologic deficit. To be effective, such a drug must also cross the blood-brain barrier in order to reach the cerebral arterial smooth muscle cells. Its inhibition should be selective and not affect the contractions of systemic arteries to the extent that severe hypotension occurs.

In Vitro Study of Contractions of Large Cerebral Arteries

We developed a chamber that allowed us to measure the isometric contractions of large cerebral arterial segments. The chamber is designed so that arterial

From the Department of Neurosurgery, Vanderbilt University, Nashville, Tennessee. This study was supported in part by grants from the National Foundation of the March of Dimes, United Cerebral Palsy Research and Educational Foundation and Miles Pharmaceuticals Company (American subsidiary of Bayer).

segments 3 to 4 mm in length are placed over 2 stainless steel prongs so that a constant resting tension can be developed and isometric contractions measured. The arterial segments are bathed by buffer, and the temperature is kept constant. Aliquots of vasoactive agents to be tested can be added to the chamber bath and dose-response curves to these agents can be determined from the increase in contractile activity of the segments. Our initial experiment showed that canine basilar and middle cerebral artery segments gave dose-dependent contractions to a variety of agents, including serotonin, prostaglandin $F_{2\alpha}$, prostaglandin A_1, bradykinin, epinephrine and norepinephrine, histamine and potassium chloride.[1] Of all the agents tested, serotonin was found to have the smallest $K_{ED_{50}}$. Next, we demonstrated that cerebrospinal fluid taken from patients several days after a subarachnoid hemorrhage would cause dose-dependent contractions of canine basilar arteries. In contrast, cerebrospinal fluid collected from patients undergoing lumbar myelography had no contractile activity.[2] Most contractile activity in these cerebrospinal fluid samples was shown by paper chromatography in 3 separate solvent systems to be due to serotonin. We carried out a similar series of experiments on cerebral arterial segments from 6 persons obtained within an hour of death at autopsy.[3] The response of the human arterial segments was strikingly similar to that of the canine arterial segments (Fig. 1). The human arterial segments also responded in a dose-dependent fashion to cerebrospinal fluid collected from 2 patients several days after their hemorrhage who had delayed ischemic neurologic deficits and angiographically demonstrated spasm (Fig. 2).

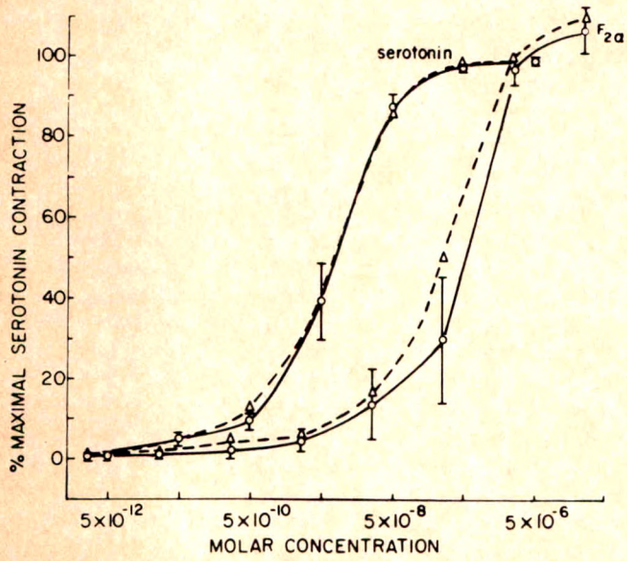

FIGURE 1. Mean cumulative log dose-response curves of human cerebral arteries (**solid lines**) and canine basilar arteries (**dashed lines**) for serotonin and prostaglandin $F_{2\alpha}$. Number of arteries tested are as follows: serotonin on human arteries = 6, $F_{2\alpha}$ on human arteries = 5, serotonin on canine arteries = 4, F_2 on canine arteries = 4. Brackets = standard error of the mean (SEM); 100% response to serotonin = 12.2 g ± 1.6 SEM. Reprinted with permission from *J Neurosurg.*[3]

The results demonstrate that human and canine large cerebral arteries are capable of contracting in a dose-dependent fashion in response to a variety of vasoactive agents. Furthermore, they demonstrate that the canine cerebral arteries are a good model for studying the contractile mechanisms of human cerebral arteries. They also demonstrate that cerebrospinal fluid taken from patients several days after a subarachnoid hemorrhage would cause significant contraction of large cerebral arteries, and that most contractile activity was due to serotonin in the cerebrospinal fluid.

Studies were then carried out with such classic serotonin antagonists as methysergide and cyproheptadine.[2] These serotonin antagonists were not as effective at low concentrations in inhibiting the serotonin-induced contraction of large cerebral arteries. We were initially puzzled by these results. It was recently documented, however, that there are 2 different serotonin receptors, a high affinity 5-HT_1 receptor and a low affinity 5-HT_2 receptor, and we recently showed that canine basilar arteries use the high affinity 5-HT_1 receptor in their contractile response to serotonin.[4] At the present time, there are no known 5-HT_1 receptor antagonists. All of the classic serotonin antagonists have been shown to antagonize the lower affinity 5-HT_2 receptor; this explains their lack of effectiveness on large cerebral artery segments.

Determination of the Source of "Activator" Calcium for Large Cerebral Arteries

From the available experimental data, it appears that the concentration of free calcium present at the actin and myosin filaments determines the degree of contraction at any given moment. By regulating the amount of intracellular free calcium present at the site of the contractile proteins, the smooth muscle cell is able to regulate the amount of contraction. This "activator" calcium can come from 2 different sources: extracellular calcium or bound intracellular calcium. Van Breemen et al[5] have shown that lanthanum effectively blocks the passage of extracellular calcium into the vascular smooth muscle cell, and, further, that it binds all of the extracellular sites that normally hold calcium. They also showed that norepinephrine, angiotensin and histamine produce 1 contraction after the application of lanthanum to strips of rabbit aorta. After this 1 contraction, no further contraction could be produced regardless of which agent was used. They interpreted this result as showing that norepinephrine, angiotensin and histamine were able to use a common intracellular pool of calcium, which was replaced by extracellular calcium. This replacement was blocked by lanthanum.[5] We[6] repeated this experiment using canine basilar artery segments and serotonin, phenylephrine and prostaglandin $F_{2\alpha}$. We were unable to obtain any contraction after the application of lanthanum with any of these 3 vasoactive agents.[6] Additional experiments demonstrated that the removal of calcium from the bath buffer also prevented most of the contraction obtained with these 3 agents. We concluded that, unlike the rabbit aorta, large cerebral arteries use primarily extracellular calcium as the source of activator calcium. Subsequently, we repeated these experiments using canine femoral arterial segments and determined that they behave much like the rabbit aorta. After the application of lanthanum, a single contraction or a series of decreasing contractions could be obtained. The removal of calcium from the bath buffer did not initially cause much decrease in the amount of contraction obtained with these vasoactive agents.

These results suggested that the newly developed calcium antagonists might selectively block the contractions of large cerebral arteries without affecting the contractions of systemic arteries to the extent that severe hypotension would occur.

The initial experiments were carried out with nifedipine because it was the most potent of the then known calcium antagonist group of drugs.[7] We demonstrated that nifedipine in a dose-dependent fashion inhibits the contractions of the basilar artery to serotonin, phenylephrine and potassium chloride. In contrast, nifedipine at a concentration that effectively inhibited the basilar artery (3×10^{-8} M) did not significantly inhibit the contractions of the femoral artery induced by serotonin and phenylephrine. Potassium chloride contractions were significantly inhibited in the femoral artery by nifedipine. High potassium contractions had been previously shown to induce contractions in a variety of smooth muscle cell preparations by causing an influx of extracellular calcium.[8]

TABLE I Changes in Cross-Sectional Area (radius^2/control radius^2) of Basilar and Ventral Spinal Arteries of Dogs After the Subarachnoid Injection of Blood and Treatment with Nifedipine*

Time of Angiogram (±10 minutes)	% of Control	
	Basilar	Ventral Spinal
Control (n = 3)	100	100
30 minutes after SAH	73 ± 7	50 ± 10
80 minutes after SAH	71 ± 7	48 ± 15
Control (n = 4)	100	100
30 minutes after SAH	52 ± 9	50 ± 10
80 minutes after SAH 30 minutes after nifedipine	133 ± 27	122 ± 17
Control (n = 4)	100	100
30 minutes after SAH 50 minutes after nifedipine	135 ± 21	127 ± 21
Control (n = 4)	100	100
2 days after SAH	57 ± 7	52 ± 9
2 days after SAH 30 minutes after nifedipine	111 ± 8	96 ± 8

* 1 mg/kg of nifedipine placed under the tongue of the dogs.
SAH = subarachnoid injection of 2.5 ml blood. Reprinted with permission from *Neurosurgery*.[9]

In vivo studies were then carried out in dogs.[9] The dogs were sedated with intravenous sodium pentobarbital and intubated; a vertebral artery was then selectively catheterized using a femoral artery approach. A control angiogram of the cerebral circulation was obtained, and then a subarachnoid hemorrhage was produced by inserting a 20-gauge spinal needle into the cisterna magna and injecting 2.5 ml of fresh whole blood from the dog being studied. Subsequent angiograms taken at varying time intervals showed that after the subarachnoid hemorrhage, spasm was produced. Nifedipine dissolved in polyethylene glycol 400 was administered sublingually, and angiograms were taken 30 minutes later. This study demonstrated that nifedipine, at a concentration of 1 mg/kg, was capable of both preventing and reversing the short-term spasm. It was also effective in reversing spasm seen 2 days after the hemorrhage (Table I). The large and consistent effect of nifedipine allowed the results from only 4 dogs in each experimental group to be statistically significant. In addition, the results in each experimental group supported the results of the other experimental groups, and the in vivo results confirmed the earlier in vitro results with nifedipine. Significant hypotension did not occur in the dogs given sublingual nifedipine.

The Bayer Pharmaceutical Company was consulted concerning a clinical trial of nifedipine in patients after a subarachnoid hemorrhage. They suggested that an analogue of nifedipine, now known as nimodipine, might be even more effective on cerebral arteries. We carried out additional in vitro and in vivo studies comparing nimodipine with nifedipine.[10,11] Nimodipine was found to inhibit the serotonin-induced contractions of the canine basilar artery at nanomolar concentrations (Fig. 3). In contrast, even at micromolar concentrations, it had very little effect on serotonin-induced contractions of the canine femoral artery (Fig. 4). Studies were also carried out using human frontal cortex to study the binding of tritiated nimodipine.[12] Nimodipine was found to have a K_i of 0.29 nM and nifedipine a K_i of 1.0

TABLE II Correlation Between Nimodipine's Binding and Its Inhibitory Effect on the Basilar Artery

	H^3 Binding Human Brain Apparent K_i (nM)	Chamber	
		Dog Basilar Artery IC_{50}(nM)	Dog Femoral Artery IC_{50}(nM)
Nimodipine	0.29 ± 0.07	0.20	>10,000
Nifedipine	1.0 ± 0.3	6.2	2,600

nM. The correlation between nimodipine's binding and its inhibitory effect on the basilar artery is striking (Table II). At a concentration of 0.29 nM, one half of the binding sites are occupied by nimodipine; at a similar concentration of 0.20 nM in the chamber, nimodipine has one half of its maximal inhibition of the basilar artery's contractile response to serotonin. In contrast, nifedipine does not have as high an affinity in binding studies and has even less of an effect on the canine basilar artery with an IC_{50} of 6.2 nM. Its effect on the canine femoral artery is also greater than nimodipine's. Subsequent in vivo studies of nimodipine and nifedipine again demonstrated that a sublingually administered dose of 0.28 mg/kg of nimodipine was more effective in reversing angiographic spasm than nifedipine at this same dose. An additional potential benefit of nimodipine is that it is more lipid soluble than nifedipine and therefore might cross the blood-brain barrier more readily.

These results led us to choose nimodipine for a prospective trial in patients who had had a subarachnoid hemorrhage from a ruptured intracranial aneurysm.

Controlled Trial of Nimodipine in Patients After a Subarachnoid Hemorrhage

One hundred twenty-five patients from 5 institutions were enrolled in a prospective, double-blind, randomized, placebo-controlled trial of nimodipine. Each had a subarachnoid hemorrhage from a ruptured intracranial aneurysm.[13] The study was designed as an explanatory trial and not a management trial.[14] The objective was to determine if nimodipine was effective in either preventing or altering the severity of ischemic neurologic deficits caused by spasm. Only patients who were neurologically normal according to study criteria were entered so that the development of the neurologic deficit could be accurately determined. A subarachnoid hemorrhage from the aneurysm had to have occurred within 96 hours before treatment began so that all patients were at risk for spasm. All patients were randomized in a double-blind manner to receive gelatin capsules containing either nimodipine or placebo. The dose of nimodipine was 0.35 mg/kg, rounded to the nearest full 10 mg capsule every 4 hours for 21 days.

If a neurologic deficit developed during the 21-day treatment period, the patient, within 48 hours of the occurrence, underwent a series of diagnostic tests, including CAT scan and intracranial angiography. The neurologic outcome at the end of treatment was classified as normal or severe; there was also an exclusion group termed mild or moderate for those patients with a neurologic deficit that did not meet the definition of severe. Two endpoints were defined for analysis of efficacy: the development of a neurologic deficit from cerebral arterial spasm alone and the severity of the deficit at the end of the treatment period. The following criteria were established before the trial ended: contingency table analysis with Fisher's exact test of significance would be used to examine the 2 endpoints; a two-tailed significance level (p value) <0.05 would be necessary to conclude that nimodipine was effective and the study would be terminated, regardless of the results, after 125 patients were entered.

After the study was completed and the data analyzed, it was found that randomization was effective (patients were well matched). Eight of the 60 patients given placebo either died or still had severe deficits from spasm at the end of treatment (Table III). In contrast, only 1 of the 56 patients given nimodipine fell into the severe outcome category (p = 0.03, Fisher's exact test). This analysis excluded both 5 patients with protocol violations and 4 patients who did not meet the entry criteria. If the 5 patients with protocol violations had been included, the p value would have been 0.02. The conclusion that administration of nimodipine was responsible for this difference in outcome is supported by the following findings: (1) placebo and nimodipine groups were

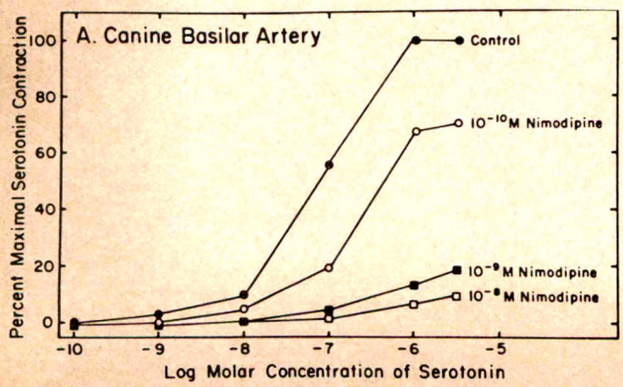

FIGURE 3. Mean cumulative log dose-response curves of canine basilar artery segments to serotonin with various bath concentrations of nimodipine. Reprinted with permission from *Headache*.[11]

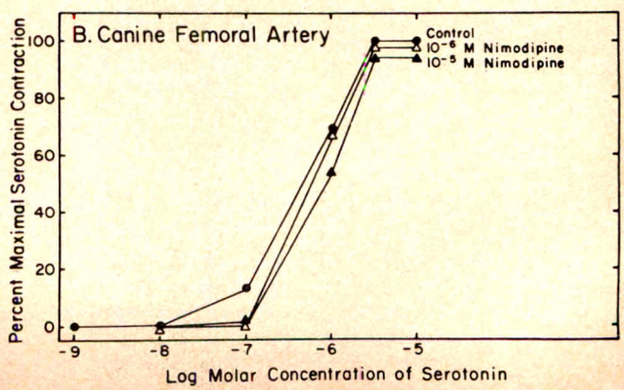

FIGURE 4. Mean cumulative log dose-response curves of canine femoral artery segments to serotonin with various bath concentrations of nimodipine. Reprinted with permission from *Headache*.[11]

similar with respect to every known factor that might have influenced either the development of neurologic deficit from spasm or the neurologic outcome; (2) nimodipine had no apparent adverse effects, and therefore, the double-blind nature of the study was maintained; (3) analysis of preentry CAT scans and angiograms of patients with neurologic deficits from spasm revealed that nimodipine was associated with a significant change in the degree of spasm seen angiographically in patients with large amounts of blood in their basal subarachnoid spaces, (4) nimodipine was present in the cerebrospinal fluid of the patients; and (5) the results of similar previous experiments in animals were consistent with the results of the clinical trial.

In this trial, nimodipine, however, did not prevent the occurrence of deficits from spasm alone. Rather, its effect was analogous to the shifting of a dose-response curve to the right. The number of patients in both treatment groups who had deficits from spasm alone was not significantly different. In contrast, there was a significant difference in the severity of the deficit between nimodipine and placebo groups. It is reasonable to suggest from these results that the dosage of nimodipine administered produced an important effect but not a maximal one. Concern about the safety of nimodipine, which had not previously been given to patients with subarachnoid hemorrhage, led us to choose a dosage that might not be maximally efficacious, according to our experiments in dogs. Because there were no serious adverse effects from nimodipine, it seemed reasonable to conduct a second explanatory trial using a higher dosage. This study is now in progress at 25 institutions in North America. Patients are receiving 30, 60 or 90 mg every 4 hours in a random manner. We hope to confirm the results of our initial trial and show a dose-dependent relation between nimodipine and the occurrence and severity of neurologic deficits from cerebral arterial spasm alone.

Several questions remain to be answered. The results of the first trial with nimodipine need to be confirmed. The oral administration may not always be the best route of administration, and trials are underway in Europe with an intravenous preparation of nimodipine as well as a topical application of a nimodipine solution to be used when cerebral artery surgery is performed. The optimal dosage of nimodipine has not been established, but we should know more after our second trial. The mechanism of action of nimodipine remains open to question. The basis for the clinical trial was nimodipine's inhibition of large cerebral artery contractions. We know from binding experiments, however, that nimodipine binding sites occur in brain tissue. It may be that, at least in part, the improved clinical results seen in patients after a subarachnoid hemorrhage are due to nimodipine's effect on neuronal tissue. Finally, nimodipine and nifedipine are both substituted 1,4 dihydropyridines. There are other calcium antagonists with different chemical structures, such as verapamil and diltiazam, that appear to bind to different sites on the calcium channels on human frontal cortex than nimodipine does.[12] The clinical efficacy of these drugs in cerebral arterial spasm remains to be determined.

TABLE III Patients Who Had Deficits From Spasm: Neurologic Outcome at End of 21-Day Treatment Period

Placebo	Nimodipine
Normal	
n = 6	n = 8
Mild to Moderate	
n = 2 Patient 1. 3/5 left hemiparesis 2. Disoriented to year	n = 4 Patient 1. Disoriented to city 2. 3/5 left arm 3. Disoriented to city, 4/5 right leg, mild aphasia 4. 4/5 left hemiparesis
Severe

Raynaud's Phenomenon: Pathophysiologic Features and Treatment with Calcium-Channel Blockers

CRAIG R. SMITH, MD, and RICHARD J. RODEHEFFER, MD

Raynaud's phenomenon may be associated with severe pain, functional disability and digital infarction, particularly in patients with underlying vascular disease. The pathophysiologic features of Raynaud's phenomenon are complex although vasospasm contributes to the production of digital ischemia in most cases. Calcium-channel blockers have been shown to produce arteriolar vasodilation and an increase in peripheral blood flow. They have been used to treat patients with Raynaud's phenomenon in several prospective, randomized, double-blind, placebo-controlled trials. Low doses of verapamil were ineffective but both diltiazem and nifedipine produced subjective improvement in 60 to 90% of cases. Objective measures of digital blood flow were not improved. Patients without underlying vascular disease responded more readily to therapy than patients with scleroderma. Adverse effects were uncommon and seldom necessitated discontinuation of therapy. These data suggest that nifedipine and diltiazem provide effective short-term improvement in symptoms for most patients with Raynaud's phenomenon.

(Am J Cardiol 1985;55:154B–157B)

Raynaud's phenomenon is characterized by the abrupt development of digital pallor or cyanosis in response to cold exposure or stress.[1,2] Ischemic symptoms such as parathesias and numbness often accompany the pallor, last as long as the stimulus is present and are followed by hyperemia, pain and throbbing of the digits. The color changes are usually sharply circumscribed, involve 1 or more fingers and may be asymmetrical. The condition may produce functional disability, digital atrophy, ulceration or gangrene, particularly in patients with underlying vascular disease. Raynaud's phenomenon may also be part of a generalized process involving the feet, ear lobes and visceral vessels of the lung, kidney or heart.

Pathophysiologic Features

The pathophysiologic features of Raynaud's phenomenon are complex (Fig. 1).[3] From Poiseuille's law it can be deduced that there are 3 mechanisms that may decrease digital blood flow: decreased perfusion pressure, increased blood viscosity or decreased luminal area of the digital artery.[4,5] Each of these mechanisms may occur individually or in combination and each may be caused by specific anatomic or functional abnormalities. Decreased perfusion pressure may be caused by systemic hypotension or proximal vascular occlusion. Increased blood viscosity may be caused by increased plasma fibrinogen, increased platelet adhesion or decreased red cell deformability.[6–9] Most often decreased flow is induced by a decrease in the luminal area of the digital artery. Decreased luminal area is caused either by anatomic vascular occlusion, vasospasm or both. Anatomic luminal occlusion is the hallmark of patients with scleroderma. These patients have intimal and advential fibrosis, but they may also have diffuse small fibrin thrombi that further impair digital flow.[10] Patients with systemic lupus erythematosis, rheumatoid arthritis and polyarteritis nodosa also have luminal obstruction due to focal vasculitis or thrombosis.

Arterial and arteriolar vasospasm is a normal response to cold exposure or stress. Vasospasm may be caused by a central adrenergic response or to changes in local mediators that control vascular smooth muscle tone. Recent data suggest that cold increases the α-adrenergic responsiveness of the digital vessels by increasing release of norepinephrine, decreasing norepinephrine degradation and possibly increasing receptor sensitivity.[11] An increase in adrenergic vasomotor tone has long been thought to be a factor in Raynaud's phenomenon. Perhaps patients with Raynaud's phenomenon have a more aggregated response making them more likely to have spasm or severe spasm.

Local mediator abnormalities including diminished prostacyclin or increased thromboxane production have also been suggested as causes for vasospasm in Raynaud's, but conclusive evidence for these abnormalities

TABLE I Double-Blind Clinical Trials of Calcium-Channel Blockers in Raynaud's Phenomenon

Report	Patients (n)	Drug	Dose (mg)	Duration (weeks)	Attack Frequency Decreased	Subjective Improvement	Objective Improvement
Kinney et al[16]	17	Verapamil	40–80 qid	2	No	No	No
Vayssairat et al[17]	26	Diltiazem	60 tid	2	Yes	Yes	. . .*
Kahan et al[21]	30	Nifedipine	20 tid	2	Yes	Yes	. . .*
Smith and McKendry[22]	17	Nifedipine	10 qid	2	Yes	Yes	No
Rodeheffer et al[23]	15	Nifedipine	20 tid	2	Yes	Yes	No

* Not measured.
qid = 4 times daily; tid = 3 times daily.

is lacking.[12] In fact, a preliminary report suggests that thromboxane is not of pathogenic importance in Raynaud's phenomenon.[13] Serotonin responsiveness has also been studied in an in vitro system. Cutaneous vascular smooth muscle strips from patients with scleroderma had an increased contractile response to serotonin compared with vascular smooth muscle strips from normal subjects. On the basis of these data, further studies of the influence of serotonin and the responsiveness of the vasculature to serotonin seem indicated.

Calcium-Channel Blockers

Both in vitro and in vivo experiments have demonstrated that calcium-channel blockers decrease vascular smooth muscle tone and relieve arterial vasospasm. Drug-induced vasodilation causes a decrease in peripheral vascular resistance and an increase in peripheral blood flow.[14] Moreover, calcium-channel blockers inhibit, in vitro, norepinephrine-induced vasospasm of rabbit and human peripheral arteries and veins.[15] Because of these unique properties, several investigators have studied the effectiveness of calcium-channel blockers in patients with Raynaud's phenomenon (Table I).

Kinney et al[16] conducted a double-blind, prospective, crossover trial in 17 patients given verapamil 40 to 80 mg 4 times a day for 2 weeks. They measured therapeutic efficacy by diary tabulation of attack frequency, subjective evaluation of overall effectiveness and digital systolic pressures. There was no significant difference between placebo- and verapamil-treated patients in the number or severity of attacks, the subjective evaluation of effectiveness or the mean digital systolic pressure during cold exposure. In this study, small doses of verapamil were used and most patients had underlying vascular disease. Further study is necessary to determine if larger doses would be more effective and to determine if patients without underlying vascular disease would be more responsive.

Vayssairat et al[17] studied diltiazem in 26 patients with Raynaud's phenomenon. Diltiazem, 60 mg, was given 3 times a day for 2 weeks in a double-blind, placebo-controlled prospective trial. This study demonstrated an improvement in patients' subjective assessment of disability and in the frequency of attacks. Symptoms decreased 17% during placebo treatment compared with 51% during diltiazem treatment and the number of vasospastic attacks decreased by 6.5 and 64%, respectively ($p < 0.05$). No objective evidence of improvement in digital blood flow was demonstrable. The investigators concluded that diltiazem was effective therapy for patients with Raynaud's phenomenon.

Matoba et al[18] have also investigated diltiazem. They conducted an open-label trial in 17 men with vibration-induced Raynaud's. Diltiazem, 30 mg, was given 3 times a day for 6 weeks. Effectiveness was assessed by subjective patient reports, skin temperature recovery

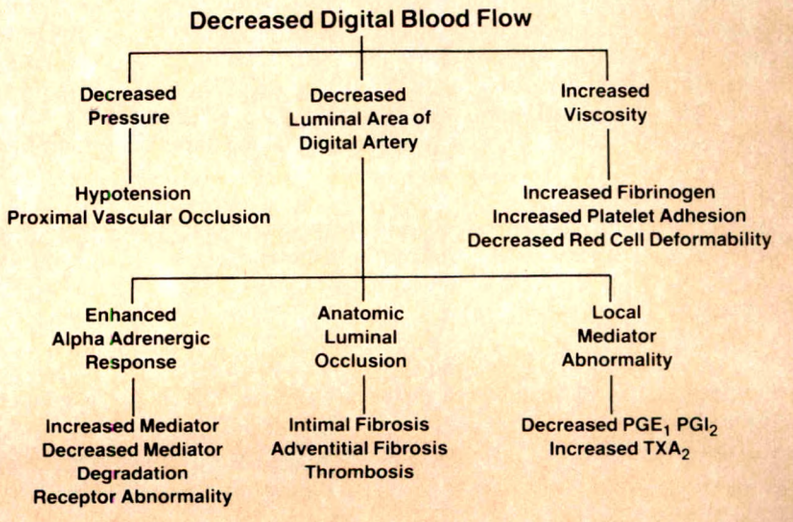

FIGURE 1. Pathophysiologic features of Raynaud's phenomenon.

TABLE II Patient Assessment of Therapeutic Efficacy

Subjective Assessment	Nifedipine n (%)	Placebo n (%)
Moderated or marked improvement	9 (60)*	2 (13)
Minimal improvement, no change or worse	6 (40)	13 (87)

* p = 0.02, Fisher's exact test.

times and digital sensory tests. Matoba observed significant ($p < 0.05$) improvement in skin temperature recovery times and sensory tests. Most notably, 69.6% of the patients judged diltiazem "effective" and no adverse effects were reported. Matoba concluded that diltiazem was effective in the long-term management of vibration-induced Raynaud's phenomenon.

Most recently, a randomized, prospective, double-blind trial of diltiazem has been reported by Kahan et al.[19] They studied 16 patients with scleroderma, rheumatoid arthritis, systemic lupus erythematosis and idiopathic Raynaud's phenomenon. Symptom severity was measured using a 10 point scale. When all 16 patients were evaluated, mean attack frequency decreased from 18.9 per 2-week period with placebo to a 12.6 with diltiazem ($p < 0.05$). Attack severity was rated 6.2 with placebo and 4.2 with diltiazem ($p < 0.05$). Patients with idiopathic disease appeared to respond more dramatically than those with an underlying systemic disease.

Three studies have assessed the effects of nifedipine in patients with Raynaud's phenomenon. Kahan et al[20] reported the preliminary results of a controlled, prospective trial in 16 patients. Nifedipine, 20 mg, was given as a single oral dose on 2 consecutive days. Vasospasm was induced by hand immersion in cold water before and at the first and sixth hour after nifedipine and placebo administration. Nifedipine delayed the onset of digital vasospasm in 14 of the 16 patients compared with placebo. A long-term, open-label study of the effectiveness of nifedipine, 20 mg 3 times daily, was then conducted with 10 patients. There was a decrease in the mean number of digital vasospastic attacks per week from 29.5 to 4.3 and 4 of the 10 patients were entirely free from attacks. Kahan et al[21] subsequently published the results of a randomized, prospective, placebo-controlled, double-blind, crossover trial in 30 patients treated with nifedipine, 20 mg 3 times daily for 2 weeks. The number of vasospastic episodes decreased 90.1% for patients with idiopathic Raynaud's phenomenon, 78.6% for patients with systemic lupus erythematosis and 64% for patients with scleroderma. These differences were statistically significant compared with placebo, suggesting that nifedipine was effective therapy for most patients with digital vasospasm, but more so in those with idiopathic Raynaud's phenomenon.

Smith and McKendry[22] conducted a prospective, double-blind, crossover trial comparing placebo with nifedipine, 10 mg 4 times daily for 2 weeks, in 17 women with idiopathic Raynaud's phenomenon, scleroderma and systemic lupus erythematosis. Effectiveness was assessed by diaries, subjective evaluation and skin temperature recovery times after cold exposure. Severity and global effectiveness were measured with 10 cm visual analogue scales in which a score of 10 indicated the greatest severity or effectiveness. The frequency of attacks decreased from 2.5 ± 0.4/day with placebo to 1.3 ± 0.3/day with nifedipine. The severity of attacks decreased from 5.8 ± 0.6 with placebo to 3.4 ± 0.5 for nifedipine, and effectiveness improved from 1.3 ± 0.6 to 5.3 ± 0.8. No improvement was measurable in skin temperature recovery times.

Finally, Rodeheffer et al[23] conducted a placebo-controlled, double-blind trial of nifedipine in the treatment of patients with Raynaud's phenomenon. Patients with digital vasospasm caused by thoracic outlet syndrome, vibratory trauma, large vessel atherosclerosis, thromboangiitis obliterans and polyarteritis nodosa were excluded from the trial. The trial consisted of 4 study periods: a placebo run-in period lasting 2 weeks followed by 2 treatment periods of 2 weeks duration each, separated by a 1-week washout period. During the treatment periods, patients received either nifedipine, 20 mg 3 times a day, or placebo. Several measurements were taken to determine the drug effectiveness. These included the patient's global assessment of drug effectiveness on a 5 point scale, diaries in which the patients tabulated the frequency and severity of their vasospastic episodes on a daily basis and digital artery systolic pressures, taken while patients were lying on a thermal blanket at 30 and 15°C. The trial was conducted during cold weather months.

The frequency of Raynaud's attacks per 2 weeks decreased from 14.7 episodes with placebo to 10.8 episodes with nifedipine ($p < 0.05$). This response was more pronounced in patients with idiopathic Raynaud's phenomenon. The patients' overall assessment of the effectiveness of nifedipine versus placebo therapy was also significantly different. Moderate or marked subjective improvement occurred in 60% of the patients with nifedipine and in only 13% with placebo, $p = 0.02$ (Table II). Despite improvement in the number of vasospastic episodes and marked improvement in the patients' global assessment of therapy, no changes could be detected in digital perfusion pressures when nifedipine and placebo were compared.

The results of these clinical trials indicate that during nifedipine treatment many patients have a decrease in the frequency of vasospastic attacks and a moderate or marked alleviation in their symptoms. However, there was variability in the response to therapy, with some patients having no response at all. Patients without underlying vascular disease appeared to respond better whereas patients with scleroderma appeared to do less well. The reason for the difference in individual responses to nifedipine cannot be determined from the data, but may be due to variation in the severity of vasospasm, variation in extent of fixed anatomic narrowing of the digital arteries, presence of active vasculitis or other as yet uncharacterized variables associated with the presence of an underlying systemic disease.

In these studies, calcium-channel blockers were conveniently administered and well tolerated. The most common adverse effects were flushing, mild headache, a sensation of light-headedness and ankle edema. Because these symptoms were usually mild and transient, they should not limit the clinical utility of these drugs in patients with Raynaud's phenomenon.

The lack of correlation between subjective alleviation of symptoms and objective evidence of improvement in digital blood flow was a consistent finding in these studies. The methods used to measure digital flow included digital sphygomomanometry, venous occlusion plethysmography and skin temperature recovery times. The reason for the failure of these methods to detect improvement is not clear. It may be that blood flow was improved during the tests but the methods were not sensitive enough to detect it, or that blood flow was not improved during the application of the tests. In each study blood flow measurements were performed after a cold challenge; in 2 studies the hands were placed in ice cold water for 20 seconds[20,21] and in 1 study patients were asked to lie on a cooling blanket at 15°C for 20 minutes.[23] These stimuli provoked digital vasospasm in most patients. Although it is possible that the blood flow measurement techniques used were insensitive, it is also possible that the magnitude of the stimuli used during the objective tests was too great to be reversed by nifedipine or diltiazem. Because the magnitude of the stimuli used during the tests was probably far in excess of the magnitude of the stimuli these patients were exposed to in daily living, it may be that calcium-channel blockers were effective in blocking the vasospastic response to mild or moderate stimuli but not to severe stimuli.

In summary, 5 independent, double-blind, controlled clinical trials have shown that short-term treatment with nifedipine or diltiazem provides symptomatic relief in many patients with Raynaud's phenomenon. Further clinical studies are needed to determine the site of drug action, the dose-response relation, the effectiveness of long-term therapy and the predictors of clinical responsiveness.

Influence of Calcium-Channel Blockers on Platelet Function and Arachidonic Acid Metabolism

JAWAHAR L. MEHTA, MD

Available data indicate that platelet function and arachidonic acid metabolism are important factors in hemostasis and regulation of vascular tone. Plasma membrane and intracellular mobilization of calcium ions are intimately related to platelet activation and release of platelet contents. Release of arachidonic acid from membrane phospholipids as well as subsequent synthesis and release of vasoconstrictor thromboxane A_2 are also regulated by movement of calcium ions. Adenosine 3′:5′-cyclic phosphate in turn controls levels of free calcium ions in platelets and regulates calcium-dependent reactions. Slow-channel calcium blockers, such as verapamil, diltiazem and nifedipine, inhibit platelet activation in vitro, and decrease platelet adhesion intravascularly. These agents have also been shown to decrease platelet nucleotide release and thromboxane A_2 generation. Some preliminary data suggest that calcium blockers also increase generation of vasodilator and platelet antiaggregant prostacyclin, which could contribute to decrease in platelet function. These effects of calcium blockers on platelet function and arachidonic acid metabolism could contribute in part to their efficacy in patients with ischemic heart disease.

(Am J Cardiol 1985;55:158B–164B)

Arterial thrombosis involves a complex interaction between blood vessels and blood components, primarily platelets. It is natural, therefore, that platelet inhibitory agents are used in disease states characterized by evidence of arterial thrombosis.

Upon injury to the vascular intima, platelets adhere to the subendothelial layers and the process of platelet activation is initiated. After the shapes change, platelets undergo release reaction during which intracellular contents like adenosine diphosphate (ADP) and thromboxane A_2 are released. Circulating platelets attach to the adhering platelets, resulting in the formation of platelet aggregates. Other blood components including white blood cells, red blood cells, thrombin and fibrin are incorporated in the platelet aggregate. Platelet activation also promotes coagulation cascade and influences vasomotor activity, resulting in arrest of bleeding. After hemostasis and repair of endothelium, platelet thrombus disaggregates. However, abnormalities in the physiologic interrelations between platelets and vessel walls, such as platelet hyperactivity or persistent endothelial injury, may result in formation of intraluminal thrombi, decrease in blood flow, tissue ischemia and injury, and perhaps atherosclerosis as well. Thus, thrombosis and atherosclerosis may be considered an extension of the normal hemostatic mechanism. In the last decade, it has become apparent that platelet-vessel wall interactions are mediated in large part by products of arachidonic acid metabolism. These products include prostaglandins, prostacyclin, thromboxane A_2, hydroxy-fatty acids and leukotrienes.

Various platelet reactions as well as arachidonic acid metabolism have been shown to depend on calcium mobilization. In this report, I review evidence for the involvement of calcium in platelet activation, and discuss the effects of drugs that interact with calcium-dependent platelet functions.

Calcium and Platelets

Several studies show that calcium ions and cyclic nucleotides are interrelated factors in the coupling of extracellular messages to intracellular responses such as platelet aggregation and the release reaction.[1–3] Such stimuli as adenosine diphosphate (ADP) and ionophore A23187 cause calcium ions to be liberated from the platelet membrane-binding sites and the dense tubular system into the platelet cytoplasm. This results in platelet shape change and reversible aggregation. High concentrations of agonists cause platelet contractile activity, which results in extrusion of platelet granular

ıtents (release reaction) and irreversible aggregation. ıtelet release reaction and irreversible aggregation dependent on intracellular calcium mobilization. As idence, deuterium oxide, which interferes with cal- ım mobilization, and chlortetracycline, which chelates racellular calcium, inhibit platelet shape change, ease reaction and aggregation caused by ADP.[4] There several intracellular storage pools of calcium, such the dense tubular system, α-granules, dense bodies d mitochondria. The mitochondrial calcium is obably not a major factor in platelet activation. Ac- ation of different processes requires calcium from ferent sources; for example, calcium released from e surface membrane is involved in platelet shape ange, and the larger intracellular pool of calcium in e dense tubular system and dense bodies is mobilized cause release reaction (Fig. 1).

After the initial stimulation of platelets with ADP, rombin and collagen, platelet membrane permeability creases with resultant influx of calcium from the ex- acellular medium, which may also participate in bsequent platelet activation. Increase in membrane rmeability occurs after the earlier release of calcium om the plasma membrane. ADP, thrombin and col- gen can, however, activate platelets in the presence ethylenediaminetetraacetic acid (EDTA), which elates extracellular calcium, suggesting that influx calcium might be the consequence rather than the use of platelet activation.

In contrast to ADP, thrombin and collagen, epi- phrine induces platelet aggregation without shape ange and secretion. In the early stages of epineph- ne-induced aggregation, there is uptake of calcium om the extracellular medium by platelets.[5] As evi- nce, epinephrine-induced aggregation is blocked by rapamil-induced blockade of calcium uptake. In the second stage of platelet activation, epinephrine also causes intracellular calcium mobilization. Thus, epinephrine-induced platelet aggregation requires an initial influx of calcium to cause internal mobilization (Fig. 1). Part of the proposed calcium-induced calcium release is due to stimulation of phospholipases by calcium. In the later stages of activation, binding of extracellular calcium to plasma membrane occurs, which is essential for platelet aggregation. This calcium binding is also necessary for interactions between clotting factors and platelet membrane.

The intracellular mobilization of calcium has several effects, including disruption of the microtubules, contraction of the calcium-dependent contractile system, fusion of the membranes of dense bodies, platelet prostaglandin generation and release of the platelet-activating factor. Of these, prostaglandin generation has received considerable attention in the last decade.

Upon platelet activation, arachidonic acid is cleaved from membrane phospholipids by action of phospholipases C and A_2. Both of these enzymes require calcium for their activity. Free intracellular calcium is a major regulatory step in the generation of arachidonic acid, which is metabolized in the platelets to cyclic endoperoxides (PGG_2 and PGH_2) and then to prostaglandins E_2, D_2, $F_{2\alpha}$ and thromboxane A_2. Thromboxane A_2 is a very potent vasoconstrictor and platelet pro-aggregant. It has been proposed that thromboxane A_2 also facilitates transport of calcium from storage sites into the cytoplasm. Adenosine 3′:5′-cyclic phosphate (cyclic AMP) promotes reuptake of calcium into the storage sites and reverses the aggregation process. Thromboxane A_2 decreases cyclic AMP and may be considered an amplifier for intracellular calcium release.

Recent studies suggest that many of the effects of calcium ions are mediated by the intracellular cal-

cium-binding protein calmodulin.[6] Calmodulin itself is not active, but it forms an active complex with calcium, the calmodulin-calcium complex. Calmodulin is indeed present in platelets[7] and inhibitors of calmodulin inhibit platelet aggregation and release reaction.[8]

Calcium, Cyclic AMP and Platelet Activation

The relation between calcium and cyclic AMP is important in the regulation of platelet activation. Cyclic AMP controls levels of free calcium in platelets and regulates calcium-dependent reactions by several mechanisms (Fig. 1). Calcium inhibits adenylate cyclase and causes a decrease in cyclic AMP. Platelet aggregation inhibitors like prostacyclin increase intracellular cyclic AMP, whereas prostaglandin endoperoxides and thromboxane A_2 inhibit cyclic AMP accumulation caused by prostacyclin and prostaglandin E_1. Agents that increase cyclic AMP levels generally inhibit thromboxane A_2 synthesis. Cyclic AMP inhibits mobilization of arachidonic acid from membrane phospholipids.[9] Cyclic AMP accumulation inhibits conversion of arachidonic acid to thromboxane A_2[10] as well. There is some evidence that cyclic AMP also prevents release of ionized calcium from the storage granules.

Calcium-Channel Blockers and Platelet Activation

Increase in intracellular calcium, which initiates the contractile process, can be due to influx of calcium or to intracellular mobilization of calcium. A group of drugs commonly known as calcium-channel blockers are now available. These agents have variable effects in different biologic tissues; however, all calcium-channel blockers share the common property of inhibiting calcium entry. In low concentrations, calcium-channel blockers inhibit transmembrane flux of calcium.[11] On the other hand, these agents at similar or higher concentrations interfere with intracellular mobilization of calcium.[12,13]

Chierchia et al[14] showed that verapamil inhibits human platelet aggregation in concentration-dependent fashion. Epinephrine and collagen-induced aggregation was inhibited more than ADP-induced aggregation. Similar observations were made by Owen,[5,15] Ikeda,[16] Mehta[17] and their co-workers. Relatively low concentrations of verapamil block transmembrane calcium flux in response to epinephrine,[5,15] probably mediated through platelet α_2 receptors.[18] In contrast, ADP, collagen and ionophore A23187-induced platelet activation (caused by mobilization of calcium from membrane and intracellular stores) is inhibited at much higher concentrations (Fig. 2). Verapamil also inhibits platelet nucleotide release and thromboxane A_2 generation (Fig. 3, Table I). In normal subjects[16] and in patients with coronary artery disease,[14] platelet aggregation and circulating platelet aggregates are decreased with the use of verapamil. It has been postulated that some of the in vivo metabolites of verapamil may contribute to its antiplatelet effects.[16,17]

Effects of 2 other calcium-channel blockers, diltiazem[19,20] and nifedipine,[21] on platelet function have also been examined. These agents, like verapamil, inhibit platelet aggregation induced by ADP, epinephrine and ionophore A23187 in supratherapeutic concentration (≥500 ng/ml). Exogenous calcium blunts the platelet inhibitory effects of these agents. Ristocetin-induced platelet activation, which is calcium-independent, is not affected; this suggests that the inhibitory effects of these agents depend on calcium mobilization (Fig. 4). Some of the in vivo metabolites of diltiazem were recently shown to exert platelet aggregation inhibitory effects,[21]

; in high concentrations. Diltiazem's weak but defi-
e inhibitory effects on platelet α_2 adrenoceptors[22]
y also be important in the effects of this and related
npounds on platelet activation.

As discussed earlier, in vitro platelet activation is
ibited by these agents at supratherapeutic concen-
tions. On the other hand, administration of usual
es of verapamil and diltiazem is associated with
rease in indexes of platelet activation.[14,16] We believe
t platelet aggregation induced by a single stimulus
vitro may not reflect the in vivo state, because it is
hly unlikely that stimuli are present in vivo in
regatory concentrations. On the other hand, it is
ely that small amounts of several stimuli act on
telets in combination. To examine this possibility,
examined the effects of different platelet stimuli in
nbination on platelets. Indeed, the combination of
stimuli, each in a very small concentration, was capable of inducing complete and irreversible platelet aggregation.[20] In this "potentiated" platelet aggregation system, very small amounts of diltiazem (50 to 100 ng/ml) significantly inhibited platelet activation (Fig. 5). Platelet thromboxane A_2 generation in response to combination of stimuli was also markedly reduced by diltiazem (Table II). This was especially evident when the "potentiated" system involved calcium ionophore A23187. Once platelet aggregation had been initiated, the concentrations of calcium-channel blocking agents required to inhibit aggregation were very high (Fig. 5). Nifedipine, another calcium-channel blocking agent, also reduced platelet aggregation and thromboxane A_2 synthesis when platelets were stimulated with ionophore A23187 plus ADP or epinephrine. This inhibition was evident at concentrations of 100 to 500 ng/ml.

These studies indicate that calcium-channel blocking agents have important inhibitory effects on platelet activation mediated by calcium, especially when a variety of stimuli are used in combination. Inhibition of α_2 receptors by calcium-channel blockers may also contribute to the platelet inhibitory effects of these agents.

Another potential mechanism by which calcium-blocking agents may reduce platelet activity is stimulation of prostacyclin release. In an interesting study in dogs, Kai et al[23] correlated the peripheral vasodilator effects of the calcium-channel blocker verapamil with increases in plasma levels of 6-keto-$PGF_{1\alpha}$, a stable metabolite of prostacyclin. Pretreatment of dogs with indomethacin reduced the effects of verapamil on peripheral vascular resistance and plasma levels of 6-keto-$PGF_{1\alpha}$, suggesting that the vasodilation caused by verapamil was mediated in part by the prostaglandin system. We have examined the effects of diltiazem on prostacyclin release in fresh human umbilical vein rings by incubating them with diltiazem followed by treatment with prostaglandin substrate arachidonic acid. This caused a marked increase in prostacyclin release in the supernatants.[24] The magnitude of increase in prostacyclin release, measured as 6-keto-$PGF_{1\alpha}$, was dependent on the concentration of diltiazem, and was inhibited by cyclo-oxygenase blocker indomethacin (Fig. 6). The mechanism of increase in prostacyclin by calcium blockers is not clear, but it is possible that the inhibition of vascular thromboxane A_2 by mechanisms similar to those in the platelets may have diverted cyclic endoperoxides to the prostacyclin pathway. Increase in prostacyclin, regardless of the underlying mechanism, could contribute to the decrease in platelet activity seen in man after administration of verapamil or diltiazem.

Pumphrey et al,[25] from the Mayo Clinic, have provided additional direct evidence for inhibition of platelet activation by calcium-channel blockers in dogs with prosthetic arterial graft.[25] Groups of dogs were treated with placebo, verapamil, dipyridamole or nifedipine. The platelet deposition on the proximal anastomosis site, proximal graft, mid graft, distal graft and distal graft anastomosis site was quantitated. The

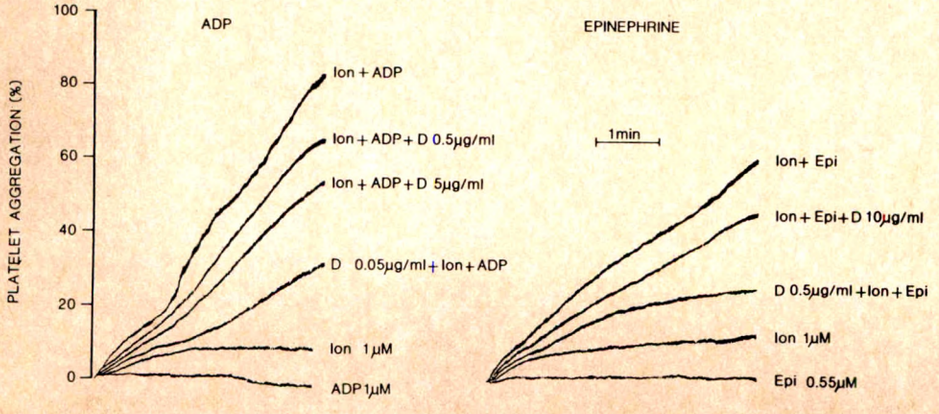

FIGURE 5. Diltiazem and ionophore A23187-induced potentiation of adenosine diphosphate (ADP)-stimulated platelets (**left**) and epinephrine-stimulated platelets (**right**). ADP, epinephrine (Epi) and ionophore A23187 (Ion) were used in subthreshold concentrations. Small concentrations of diltiazem (D) (0.05 to 0.5 μg/ml) added to platelets before ionophore A23187 potentiation of inhibition. In contrast, very large concentrations of diltiazem were required once the potentiation had begun. Reprinted with permission from *J Lab Clin Med.*[20]

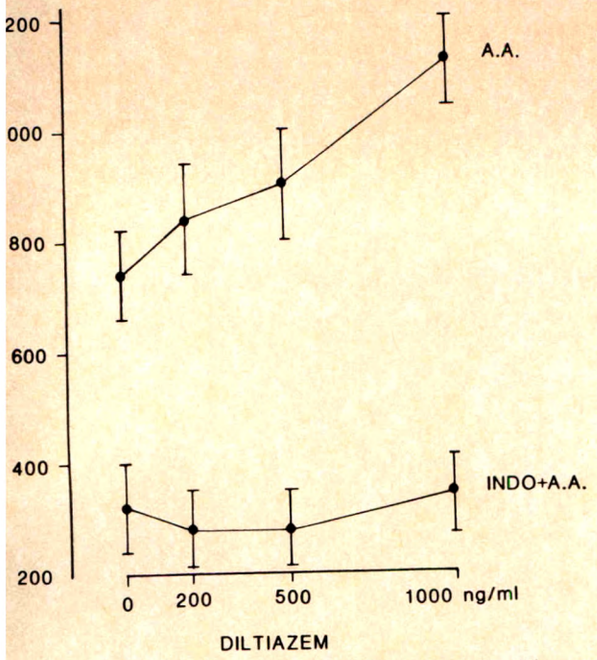

GURE 6. Stimulation of prostaglandin (PGI_2) release by diltiazem asured as 6-keto-$PGF_{1\alpha}$, stable hydrolysis product of PGI_2, in vascular g supernatants. Increase ($p < 0.02$) in PGI_2 release was dose-dendent (200 to 1,000 ng/ml of diltiazem). Pretreatment of umbilical n rings with indomethacin (INDO) inhibited ($p < 0.01$) control (buffer diluent for diltiazem) as well as diltiazem-associated increase in PGI_2 ease. Data are summary of 7 different experiments. Data are exssed as mean + standard error. AA = arachidonic acid.

atelet deposition on the graft as well as on the distal aft site was significantly inhibited by dipyridamole would be expected (Fig. 7). Both verapamil and nidipine caused similar and equipotent inhibition of latelet deposition on the prosthetic grafts.

In summary, available data indicate that intracellular calcium concentrations influence arachidonic acid metabolism, cyclic AMP and eventual platelet activity. Calcium-channel blocking agents inhibit platelet activation, cyclic nucleotide release and thromboxane A_2 generation. These phenomena are more readily apparent when low concentrations of multiple platelet stimuli are used in combination. Enhancement of prostacyclin release by calcium blockers may be an additional mechanism of inhibition of platelet activation. These platelet inhibitory effects of calcium-channel blocking agents may contribute to their therapeutic efficacy in man.

Modification of Experimental Atherosclerosis by Calcium-Channel Blockers

WILLIAM W. PARMLEY, MD, STEVEN BLUMLEIN, MD, and RICHARD SIEVERS, BS

The process of atherosclerosis, although not completely understood, is being clarified. A unifying hypothesis holds that the initial event is endothelial injury, followed by platelet aggregation and release reactions. This leads to smooth muscle cell migration into the intima and replication, with subsequent secretion of elastin, collagen and glycosaminoglycans (which binds lipids). Several animal studies have shown that calcium plays an important role in this process. Many drugs with diverse properties can inhibit experimental atherosclerosis. These drugs appear to reduce intracellular calcium. The calcium-channel blockers nifedipine, diltiazem and verapamil, which decrease intracellular calcium, also protect animals from experimental atherosclerosis. The relevance of these animal models to human atherosclerosis is uncertain, and there are very few studies concerning regression of atherosclerosis by interfering with calcium fluxes. Further studies will be needed to clarify these points.

(Am J Cardiol 1985;55:165B–171B)

Atherosclerosis and its consequences continue to be the major cause of death in the United States. It appears to develop over much of the lifetime of a patient, and its development is related to well-known risk factors, especially heredity, hyperlipidemia, hypertension, cigarette smoking and diabetes mellitus.

Over the past several years, multiple studies have documented that increased calcium content of the arterial wall appears to enhance the process of atherosclerosis. Decrease in arterial wall calcium content by a number of pharmacologic agents can ameliorate the development of atherosclerosis in a number of different animal models. More recently, the calcium-entry blockers have demonstrated their ability to modify the atherosclerotic process. This report briefly reviews the role of calcium in the development of atherosclerosis and discusses the data that demonstrate that calcium-entry blockers can attenuate the atherosclerotic process in experimental models.

Pathogenesis of Atherosclerosis

Although the process of atherosclerosis is still not completely understood, a number of major advances have been made in understanding the various processes that are part of this pathologic development.[1–3] Although there is still some disagreement, the fatty streak that appears in children is the probable precursor of the atherosclerotic fibrous plaques that develop later in life. The fatty streak is in part associated with the migration of monocytes (macrophages) and smooth muscle cells through the endothelial layer, which then take up lipid, forming foam cells. The macrophages and smooth muscle cells contain lipids primarily in the form of cholesterol and cholesterol ester. It is probable that much of the lipid within fatty streaks comes from the plasma, although the lipids may be hydrolyzed and reesterified once taken up by cells.

One unifying hypothesis of the pathogenesis of atherosclerosis holds that the initial precipitating step is injury to the endothelium. This can be caused by a number of processes, including mechanical injury, hypercholesterolemia, homocysteinemia and immune injury, among others. Over time, fibrous plaques appear; they are markedly increased and protrude into the lumen. The plaque consists primarily of an accumulation of smooth muscle cells laden with lipid, primarily cholesterol and cholesterol esters. The cells are also surrounded by lipid, collagen, elastic fibers and glycosaminoglycans. The cells and extracellular matrix form a fibrous cap that covers a larger, deeper deposit of extracellular lipid intermixed with cell debris.

The precise sequence of events in the formation of this plaque is not totally clear. It is probable that injury

TABLE I Effects of Calcium-Altering Agents on Experimental Atherosclerosis

Investigator	Animal Model	Drug	Mechanism Postulated	Result
Whittington-Coleman and Carrier[4]	Cholesterol-fed rabbits were given oral reserpine, guanethidine or a reserpine analogue	Reserpine, reserpine analogue, guanethidine	Decreased binding of calcium at the cell membrane and elastic tissue	Fat deposition, calcium content and intimal lesions in the aorta were decreased
Whittington-Coleman et al[5]	Rabbits were fed a normal or cholesterol diet with or without intraperitoneal propranolol	Propranolol	Propranolol may have direct action on some metabolic process involving calcium in the vascular wall; the hypotensive property of propranolol prevents further complication of the process	Propranolol decreased the severity of aortic plaques and decreased aortic calcium levels
Morrison et al[6]	Rats fed a normal or cholesterol diet with or without intraperitoneal propranolol	Chondroitin sulfate A	Unknown, not due to lowering of serum cholesterol	Chondroitin sulfate A prevented aortic lesions without lowering serum cholesterol
Rosenblum et al[7]	Rabbits fed cholesterol, vitamin D and nicotine with or without subcutaneous EHDP	EHDP	If arterial calcification is inhibited, so are the other morphologic changes in the arteries	EHDP normalized hypercalcemia and decreased calcification and plaque formation in medium sized arteries; serum lipid levels unchanged
Potokar and Schmidt-Dunker[8]	Oral diphosphonates given to rats after oral vitamin D-induced aortic and renal calcification	Diphosphonic acids	Diphosphates may affect cell permeability to calcium and may affect calcium dependent processes in the cell; treatment prevents in vitro crystallization of hydroxyappatite and so inhibits aortic calcification	Diphosphonates decreased calcification in aortas and kidneys
Chan et al[9]	Rabbits fed cholesterol with or without thiophenes	Thiophenes	Decreased formation of calcium phosphates in arteries; decreased lipid and connective tissue accumulation and decreased cell proliferation due to low CA^{++} and low $PO_4^{=}$; low Ca^{++} and $PO_4^{=}$ may be due to action on adenyl cyclase-cAMP system	Thiophenes normalized the increased calcium level seen in cholesterol-fed rabbits and inhibited atherosclerosis
Wartman et al[10]	Rabbits fed cholesterol for 11 weeks, then normal chow with or without subcutaneous Mg EDTA	Mg EDTA	Mg EDTA decreases extracellular calcium causing an increased PTH level; PTH affects collagen and elastin	Mg EDTA caused plaque regression and decreased aortic collagen and elastin
Kramsch & Chan[11]	Rabbits fed a cholesterol diet with EHDP and/or colcimid	EHDP, colcemid	Cell proliferation and mobility was decreased; secretion of connective tissue proteins was decreased; calcium deposition in elastica and cholesterol binding to elastin protein are decreased	Treatment normalized the increased serum calcium level seen in cholesterol-fed rabbits; aortic accumulation of lipids, calcium, collagen, elastin and glycosaminoglycans were decreased
Kramsch et al[12]	Macacque monkeys fed cholesterol with or without lanthanum or diphosphonates	Diphosphonates, lanthanum	Same as above[11]	Treatment decreased or prevented gross and microscopic atherosclerosis and decreased aortic cholesterol, collagen, elastin and calcium

Kramsch et al[13]	Rabbits fed cholesterol with or without lanthanum	Lanthanum	Lanthanum displaces and replaces calcium on cell membranes and so inhibits calcium-dependent cellular and extracellular responses involved in the atherosclerotic process	Lanthanum decreased or prevented gross and microscopic atherosclerosis; decreased aortic cholesterol, collagen, elastin and calcium; decreased cholesterol, calcium and polar amino acids in elastin
Henry and Bentley[14]	Rabbits fed cholesterol with or without nifedipine	Nifedipine	Nifedipine decreases calcium accumulation in arterial walls and so decreases atherosclerotic lesion formation	Nifedipine decreased aortic cholesterol levels and plaque formation
Ginsberg et al[15]	Rabbits fed cholesterol with or without diltiazem, lanthanum, or flunarizine	Diltiazem, lanthanum, flunarizine	Blockade of calcium influx	All 3 drugs decreased lipid deposition in the aorta but not in the intramural coronary arteries
Rouleau et al[16]	Rabbits fed cholesterol with or without lanthanum or verapamil (oral and subcutaneous)	Verapamil, lanthanum	Verapamil may act by affecting calcium-dependent cellular process, decreasing the shear stress on the arterial endothelium, inhibiting platelet function, some other process	Oral plus subcutaneous verapamil inhibited aortic atherosclerosis

cAMP = cyclic adenosine monophosphate; EDTA = ethylenediaminetetraacetic acid; EHDP = ethane-1-hydroxy-1, 1-diphosphonate; PTH = parathormone.

to the endothelium always permits the development of such a lesion. With the loss of the endothelial barrier, platelet aggregation at the site of injury occurs, followed by the release of platelet-derived growth factor, which leads to the migration of smooth muscle cells from the the media to the intima, and subsequent smooth muscle cell mitosis. These smooth muscle cells secrete elastin, collagen and glycosaminoglycans. Glycosaminoglycans and elastin have a marked propensity to bind low-density lipoproteins, which may be important in the extracellular deposition of lipids during lesion formation. Over time the lesion may develop into a so-called complicated lesion, which is the late state of a fibrous plaque, characterized by hemorrhage, calcification, cell necrosis and mural thrombosis. This latter lesion is frequently associated with occlusion of the involved artery.

Role of Calcium in Atherosclerosis

The role of calcium in this process is a potentially important one. It should be remembered that normally there is an approximately 10,000-fold concentration gradient for calcium, when comparing the high levels in plasma to the low intracellular levels. During any kind of cell injury with membrane damage, the movement of calcium from the outside of the cell to the inside is a common occurrence, and increased calcium concentration can be demonstrated in all damaged tissue. The atherosclerotic plaque is no exception; extensive calcification is observed in these lesions. Even before this extensive influx of calcium, however, there is evidence that increased calcium in the arterial wall may accompany the process of atherosclerosis, at least experimentally. When present in increased amounts, calcium may damage cells by a number of processes, including the depression of mitochondria, with a decrease in the formation of high energy adenosine triphosphate. Presumably, decreases in high energy phosphates lead to the loss of cellular structure and function. In addition, calcium activates various enzymes, which may also be deleterious to cellular function.

Calcium has been implicated in a number of the steps related to the process of atherosclerosis. This includes aggregation of platelets, release of platelet-derived growth factor, smooth muscle cell replication, lipid binding to macromolecules and protein synthesis, to mention just a few. It is reasonable to suppose, therefore, that decrease in the influx of intracellular calcium might have a beneficial role in decreasing the degree of atherosclerosis (Table I).

In this regard, it has been appreciated for some time that catecholamines increase intracellular calcium as part of their effect on receptors. It seems reasonable to expect, therefore, that a decrease in the effects of cathecholamines might tend to decrease vascular calcium. Whittington-Coleman and Carrier,[4] for example, studied the effects of reserpine, 0.1 mg/kg/day, a reserpine analog, or guanethidine, 1 mg/kg/day (each capable of depleting tissue catecholamine), on the development of aortic atherosclerosis in rabbits. Rabbits were fed a 2% (by weight) cholesterol diet for a period

of 10 weeks. Blood lipid levels were unchanged by the 3 drugs. In general, a mild decrease or no significant change occurred in blood pressure. Analysis of the aorta demonstrated a significant decrease in aortic tissue calcium, and a decrease in the degree of atherosclerosis.

Additional studies were carried out by these investigators[5] on the same animal model with propranolol, a β-adrenergic blocker. Results also showed that the calcium content of the aortas of the treated animals was less than that of the control animals fed the high lipid diet. Similarly, the atherosclerotic lesions were less severe than those of the control group. These data further support the notion that catecholamines or increased calcium entry (or both), or intracellular release, may play an important role in the atherosclerotic process, and that inhibition of the cathecholamine effects may be partially protective.

A number of studies have evaluated substances that share the ability of being capable of decreasing the degree of calcification of the aorta, but otherwise differ markedly. Morrison et al[6] studied young adult rats in whom a high lipid diet and hypervitaminosis D led to the development of severe lesions in the coronary arteries and aorta. When the diet was supplemented with chondroitin sulfate A (1%), lipid-containing coronary lesions were markedly decreased. There was no decrease in plasma or liver lipid levels in the animals who had protection. Chondroitin sulfate A has been noted to inhibit the deposition of calcium in the connective tissue of rats.

Using a hypervitaminosis D, nicotine and hypercholesterolemic diet in the rabbit, Rosenblum et al[7] noted the effectiveness of disodium ethane-1-hydroxy-1, 1-diphosphonate (EHDP) in preventing atherosclerosis. EHDP inhibited arterial calcification and development of lipid plaques, although it had no effect on serum cholesterol and triglyceride levels. EHDP also inhibited the vitamin D-induced hypercalcemia. Although there was a decrease in the severity of lesions in medium-sized arteries, there was little effect in the aorta. As a group, the diphosphonates are effective inhibitors of a number of different types of pathologic calcification and presumably work in this model by decreasing the amount of intracellular calcification which occurs in the arterial wall.

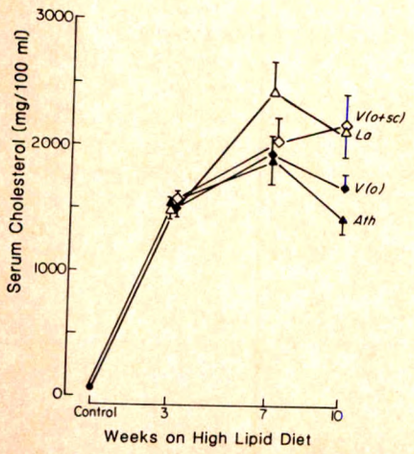

FIGURE 1. Average serum cholesterol levels in each group before (control) and after 3, 7 and 10 weeks on cholesterol-rich diet. Ath = atherosclerotic control; La = lanthanum; V(o) = oral verapamil; V(o + sc) = oral + subcutaneous verapamil. Reproduced with permission from *JACC.*[16]

Additional studies by Potokar and Schmidt-Dunker[8] showed that 3 diphosphonic compounds were able to inhibit the vitamin D-induced calcification of aortas and kidneys in rats. These compounds were chosen because of their ability to prevent in vitro crystallization of hydroxyapatite. In vivo, they also proved to be effective in inhibiting aortic calcification. In fact, selection of the compounds by their in vitro effectiveness was reasonable guidance for their effects in vivo.

Chan et al[9] studied the effect of thiophene compounds. These compounds have marked hypocalemic and hypophosphatemic effects in rats, and in tissue culture inhibit spontaneous and parathyroid-induced bone resorption. An apparent mechanism of action is an inhibition of calcium transfer out of bone. In rabbits fed high lipid diets, all of the thiophene compounds tested normalized an increased serum calcium level, although there was no effect on cholesterol levels. In the aorta, the compound inhibited all aspects of the atherosclerotic process, as determined morphologically and biochemically. There was no bone resorption noted in the treated groups. The close correlation between decrease in calcium deposition in the aorta and decrease in lesions strongly argues for the role of calcium in the atherosclerotic process. Certainly, these drugs do not work by affecting cholesterol levels. Wartman et al[10] have indicated that treatment with the calcium chelator ethylenediaminetetraacetic acid (EDTA) also inhibited and regressed plaque formation in rabbits with dietary-induced atherosclerosis.

Kramsch and Chan[11] also studied EHDP and colcemid in rabbits on a high lipid diet. Although each drug alone was somewhat effective, the combination of EHDP and colcemid virtually stopped the atherosclerotic process. It is possible that the beneficial effects of colcemid may be explained by its ability to disrupt microtubules. Like colchicine and vinblastin, colcemid binds to tubule subunits and disrupts the microtubular assembly. This may suppress proliferation and mobility of cells, as well as the ability for endocytosis and secretion of connective tissue proteins, possibly also of glycosaminoglycans. Because both drugs decreased elevated serum and arterial calcium contents in rabbits, this may be the common mechanism of action.

After initial studies in rabbits, studies were undertaken in monkeys to evaluate the effect of agents that inhibit arterial calcium deposition. Kramsch et al[12,13] showed that the diphosphonates and lanthanum were effective in decreasing arterial wall calcium and the degree of atherosclerosis. Because the rabbit has been criticized as a model of atherosclerosis, the extension of these studies to monkeys is important in demonstrating the same process in relation to calcifying agents.

It was noted that aortas from monkeys treated with diphosphonates or lanthanum, a calcium antagonist, contained smaller amounts of collagen, elastin, cholesterol, calcium and deoxyribonucleic acid (DNA) than the aortas from untreated animals. Lanthanum attaches to cell membranes and displaces calcium from the membranes, thus decreasing migration of calcium intracellularly.

Effects of Calcium-Entry Blockers in Experimental Atherosclerosis

With the increasing use of calcium-entry blockers in cardiology, it was therefore natural to evaluate the effects of these agents on experimental atherosclerosis. Three studies have been published to date using nifedipine, diltiazem or verapamil as the calcium-entry blocker.

Henry and Bentley[14] studied the effects of nifedipine on the process of atherogenesis in rabbits fed a high lipid diet. Nifedipine was given orally (40 mg/day in divided doses). Measurements of arterial pressure showed only transient changes after the oral administration of 20 mg of nifedipine. Otherwise, arterial pressures were the same in the 2 groups of animals. Similarly, the plasma cholesterol levels were the same, approximately 1,900 mg/100 ml. In the animals on the diet only, 40% of the aorta was covered with Sudan IV stained lesions, whereas in the nifedipine-treated rabbits only 17% was covered. Similarly, the cholesterol concentration in aortic tissue was decreased by nifedipine, from 47 to 29 mg/g of protein.

Ginsberg et al[15] evaluated the effects of diltiazem (103 mg/kg/day), lanthanum and flunarizine on aortic and coronary atherosclerosis of rabbits fed a 2% cholesterol diet for 10 weeks. All 3 drugs decreased lipid deposition in the aorta from 52% of the endothelial surface (control) to about 37%. Of interest was the fact that no agent suppressed atherogenesis in the intramural coronary arteries (the epicardial coronary arteries were normal in the control as well as treated animals).

In our own studies,[16] we used verapamil, another calcium-entry blocker. Rabbits were divided into 5 groups. One group was fed a control rabbit chow, and the other groups were fed an atherogenic diet containing 3% soy bean oil and 0.5% cholesterol (by weight). In order to assess the relative effect of lanthanum in our model, we gave 1 group atherogenic chow containing an average of 35 mg/kg of lanthanum trichloride daily. The low-dose verapamil group was fed an atherogenic chow containing an average of 8 mg/kg of verapamil daily. The second group had the same oral dose, but in addition had 0.25 mg/kg of verapamil given subcutaneously twice daily. The increase in serum cholesterol level is shown for the various groups in Figure 1. Note that there was an increase in all groups to a fairly high level by 3 weeks and that there was no essential difference between groups when they were killed at 10 weeks. Specifically, verapamil and lanthanum did not decrease serum cholesterol levels. In fact, the lowest level was found in the atherosclerotic control group.

At the end of 10 weeks, the rabbits were killed, the aortas removed and stained with Sudan IV. A representative aorta from each of the 5 groups is shown in Figure 2. From right to left, the aortas are those of a normal animal fed a regular diet, a control atherosclerotic animal fed a high lipid diet, the lanthanum-treated group, the low dose verapamil group (orally only) and, at the far left, the high dose group that was given both oral and subcutaneous verapamil. Note the significant decrease in atherosclerosis in the high dose verapamil-treated group, as compared with the control group.

Results from all animals are shown in Figure 3, in which the percentage of the aortic surface that was lipid-stained is plotted as a function of the serum cholesterol level. Results are presented as the mean ± standard error of the mean, and demonstrate that the serum cholesterol levels were the same in all groups of animals. There was a significant decrease in the percent involvement of the aorta from 75% in the atherosclerotic controls to 25% in the high dose verapamil-treated group. The percentage of aorta that was lipid-stained tended to be lower in the low dose verapamil and lanthanum groups than in the atherosclerotic control rabbits, but these differences were not statistically significant. Despite what appears to be a relatively high dose of verapamil given to these animals, it should be noted that the serum verapamil levels in the high dose group was quite low (12 ng/ml) compared with clinical standards (70 to 200 ng/ml). The distribution of cholesterol and triglycerides among very low density, in-

FIGURE 2. Representative aortas from different groups of rabbits showing surface area involved with atherosclerosis. termediate density, low density and high density lipoproteins was not different in the different groups of animals.

The fact that verapamil and nifedipine are distinctly different calcium-channel blockers, but have similar effects on the development of atherosclerosis, strongly supports the notion that the mechanism responsible for their salutary effects is related to their ability to reduce intracellular levels of calcium.

We removed papillary muscles from the hearts of the animals we studied, and measured their intrinsic contractile performance in a myograph. Contrary to previous reports,[17] we did not find a decrease in the intrinsic contractility of papillary muscles removed from the atherosclerotic animals. We did find, however, a slight decrease in maximum velocity of shortening in the group of animals treated with the high dose verapamil. Because these studies were conducted relatively soon after the subcutaneous administration of verapamil, it was not clear whether this was a transient or a more long-lasting depression of contractility. If the latter is the case, it might be possible that a depression of contractility could decrease shear forces on the aorta and therefore attenuate the development of atherosclerosis.

Accordingly, we have just completed a study in which we have treated animals with drugs that reduce contractility or blood pressure or both, and have measured the degree of atherosclerosis in these animals compared with a control atherosclerotic group.[18] Groups of animals were treated with metoprolol, 2.5 mg/kg/day, hydralazine, 2 mg/kg/day, and a combination of hydralazine plus metoprolol. Measurements of blood pressure showed variable effects, but there was a slight decrease in the group treated with metropolol plus hydralazine. When the animals were killed after 10 weeks on the high lipid diet, and the aortas examined, there was no significant difference between the percentage of aortic endothelial surface involved in any of the animal groups when compared with the atherosclerotic control animals. It does not appear, therefore, that any potential negative inotropic effect of verapamil is causally related to the drug's protective effect on the development of atherosclerosis. Overall, this is also suggested by the fact that nifedipine, a calcium-channel blocker with little negative inotropic effect when given in vivo, also exerts protective effects. Therefore, the data strongly suggest that the protective effects of calcium antagonists are related to a decrease in intracellular calcium.

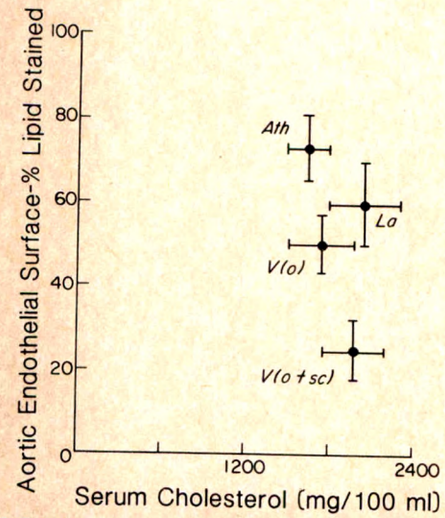

FIGURE 3. Relation of percentage of aortic surface area involved with atherosclerosis to mean serum cholesterol concentration during study. Rabbits treated with oral plus subcutaneous verapamil (V[o + sc]) had less surface area involved than did other groups ($p < 0.01$). Abbreviations as in Figure 1. Reproduced with permission from *JACC.*[16]

Most of the processes involved in atherogenesis require calcium-dependent energy from high energy phosphates. These include migration of arterial smooth muscle cells and macrophages into the intima, cell proliferation, connective tissue secretion and lipoprotein endocytosis. Calcium is also required for a number of other processes. These include the contraction-relaxation cycle in smooth muscle, directional cell movement as in chemotaxis, mitosis, adhesion of platelets to arterial connective tissue, platelet aggregation and the release phenomenon, as well as secretion of proteins, including collagen and also elastin, which binds lipoproteins to cell membrane receptors.

Elastin destruction and lesion calcification have also been suppressed by anticalcifying agents. Associated mechanisms requiring calcium include increased absorption of cholesterol by elastin due to calcium-induced changes in elastin configuration, complexing of lipoproteins to glycosaminoglycans, and calcium mineralization of connective tissue. Thus, in assessing the data from all studies cited in this review, the common theme appears to be that interventions capable of decreasing intracellular calcium exert a protective effect on the development of atherosclerosis.

Because a number of drugs given to patients can affect calcium, the potential clinical implications of these studies are evident. It should be pointed out, however, that the relevance of these animal models to human atherosclerosis is uncertain, and that there is a paucity of studies related to potential regression of atherosclerosis by interference with calcium flux. Specifically, there are no such studies available with the calcium-entry blockers. Additional studies will be necessary to determine whether or not the agents that interfere with calcium entry can also be effective in the regression process.

Effects of Calcium-Channel Blocking Agents on Left Ventricular Diastolic Function in Hypertrophic Cardiomyopathy and in Coronary Artery Disease

ROBERT O. BONOW, MD

Abnormal left ventricular (LV) diastolic performance is a characteristic feature of hypertrophic cardiomyopathy (HC) and an important contributor to the development of symptoms. Impaired diastolic filling of the hypertrophied left ventricle results from both diminished distensibility and prolonged or incomplete relaxation. LV distensibility is not only influenced by fixed anatomic abnormalities (such as fibrosis or hypertrophy) that determine the passive elastic properties of the left ventricle, but also is modulated by the dynamics of myocardial relaxation: prolonged or incomplete LV relaxation may restrict the rate and extent of LV filling and result in altered pressure-volume relations throughout diastole. Several studies indicate that impaired LV relaxation and filling in HC may be modified favorably by verapamil or nifedipine administered on a short-term basis in the catheterization laboratory, associated with improved diastolic pressure-volume relations. Verapamil also improves LV filling during oral therapy. Improved indexes of LV filling correlate with symptomatic improvement, both short-term and long-term: Approximately 80% of patients having a persistent increase in peak LV filling rate have persistent improvement in objective exercise tolerance compared with preverapamil values.

Altered LV relaxation and filling are also often observed in patients with coronary artery disease (CAD) after myocardial infarction or during acute ischemia. Moreover, impaired filling occurs under resting conditions in many patients who have normal systolic function and no evidence of previous infarction. Nifedipine improves indexes of LV relaxation and distensibility during pacing-induced ischemia and verapamil improves indexes of LV filling at rest and during exercise-induced ischemia. In both HC and CAD, improved LV diastolic function by nifedipine or verapamil may reflect reduced ischemia, improved coronary flow, alterations in LV loading conditions or primary myocardial effects. These changes may contribute to the improvement in symptoms in many patients during treatment with these drugs.

(Am J Cardiol 1985;55:172B–178B)

Diastolic function of the left ventricle in hypertrophic cardiomyopathy (HC) and coronary artery disease (CAD) has been the subject of intensive laboratory and clinical investigation. Altered left ventricular (LV) diastolic performance in these conditions results from impaired relaxation, diminished distensibility (or compliance) or both, and contributes importantly to the development and severity of symptoms. Several recent studies indicate that abnormal diastolic function in these conditions may be modified favorably by the calcium-channel blocking agents verapamil and nifedipine, which may relate, in part, to the improvement in symptoms in many patients during therapy with these drugs. Hence, it is pertinent to review the influence of LV diastolic dysfunction on the pathophysiologic features of the hypertrophied and ischemic left ventricle, and the evidence that the calcium-channel blocking drugs enhance LV relaxation and diastolic filling.

Hypertrophic Cardiomyopathy

Diminished LV diastolic filling in HC results in decreased cardiac output and increased LV filling pressures, thereby playing a pivotal role in the clinical manifestations of the disease. Two factors contribute to impaired diastolic filling of the hypertrophied left ventricle: decreased distensibility and impaired or incomplete relaxation. The dynamic influence of LV distensibility and LV relaxation on the magnitude and timing of LV diastolic filling may be examined in the context of the instantaneous relation between LV

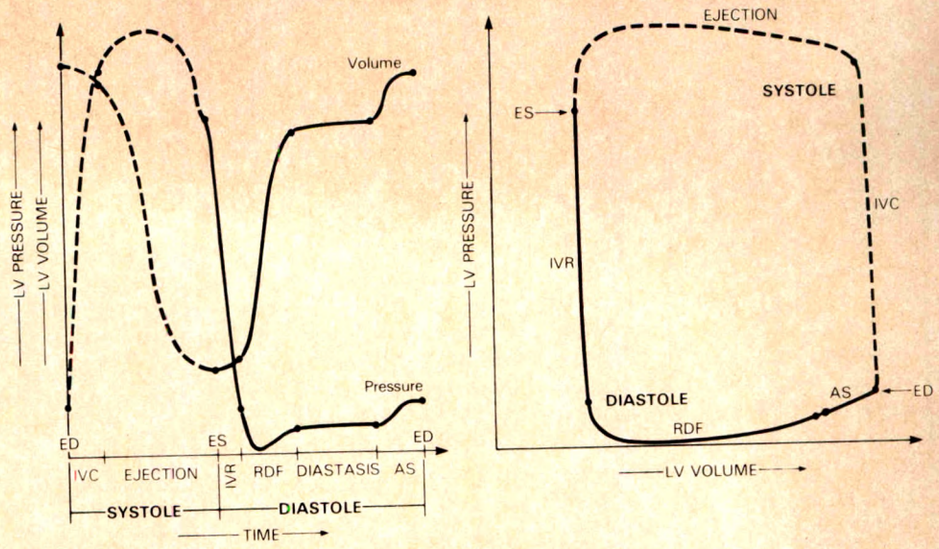

FIGURE 1. Left ventricular (LV) pressure-volume relations. **Left,** simultaneous pressure-time and volume-time curves during cardiac cycle. **Right,** instantaneous pressure-volume relation. AS = atrial systole; ED = end diastole; ES = end systole; IVC = isovolumic contraction; IVR = isovolumic relaxation; RDF = rapid diastolic filling.

pressure and LV volume throughout diastole (Fig. 1). Simultaneous LV pressure versus time and volume versus time curves during the cardiac cycle are presented in Figure 1, left, and the resultant LV pressure-volume loop, the instantaneous pressure-volume relation at each phase of the cardiac cycle,[1] is presented in Figure 1, right. LV distensibility is determined by the contour and slope of the pressure-volume relation[2,3] during the filling phases of diastole: rapid diastolic filling, diastasis and atrial systole.

LV distensibility: In HC, increased myocardial mass and altered myocardial muscle properties (stemming from fiber disarray and fibrosis) produce an increase in stiffness and a decrease in distensibility of the left ventricle,[2–5] manifested by a steeper slope of the LV pressure-volume relation during diastolic filling compared with normal. The consequence of reduced LV distensibility is an exaggerated increase in diastolic pressure during LV filling for a given increase in diastolic volume, often resulting in a diminished rate and extent of LV filling despite increased LV filling pressures.[6,7] Although LV distensibility in this regard is determined by fixed, anatomic abnormalities intrinsic to the hypertrophied left ventricle, distensibility may also be influenced dynamically by reversible alterations in LV relaxation.

LV relaxation: LV relaxation is impaired in HC[8–14] and is the second major determinant of decreased LV diastolic filling. After termination of the isovolumic phase of LV relaxation, when the mitral valve opens and the phase of rapid ventricular filling begins, the LV pressure continues to subside despite the abrupt increase in LV volume (Fig. 1, left). The decrease in pressure despite increasing volume, even in the normal ventricle, clearly indicates that active LV relaxation continues beyond the isovolumic phase and well into the filling phase, and that alterations in the extent, rate and timing of LV relaxation will have significant impact on the extent and rate of LV rapid diastolic filling.

Numerous studies indicate that LV relaxation in HC may be prolonged or incomplete,[8–14] manifested by a prolonged isovolumic relaxation period, a decreased rate of diastolic LV wall thinning and a reduced rate of LV pressure decrease, which in turn results in impaired LV diastolic filling[9–12,15,16] (Fig. 2). Decreased LV relaxation also produces an increase in myocardial tone during the filling phase, thereby altering LV diastolic pressure-volume relations.[2,5,17] Hence, LV distensibility is determined not only by fixed anatomic changes of the hypertrophied myocardium but also by potentially reversible alterations in LV filling dynamics[4] resulting from impaired relaxation.

LV relaxation is an active, energy-dependent process utilizing high-energy phosphates, directed at dissipation of muscle activation (inactivation) primarily by sequestering calcium ions in the sarcoplasmic reticulum; this lowers calcium ion concentrations in the cytosol in

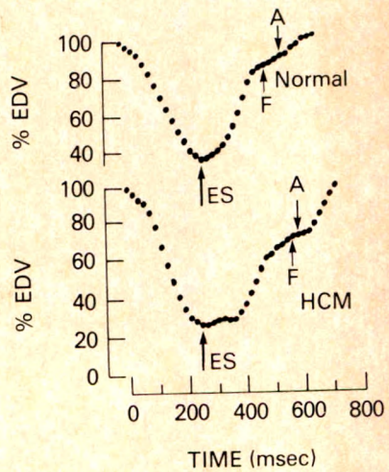

FIGURE 2. Left ventricular time-activity curves obtained by radionuclide angiography in a normal subject and a patient with hypertrophic cardiomyopathy (HCM), measuring relative volume changes throughout average cardiac cycle. Impaired diastolic function is evident in hypertrophic curve: prolonged isovolumic relaxation phase, decreased rate of rapid diastolic filling, decreased contribution of rapid filling to left ventricular filling volume and increased contribution of atrial systole. A = onset of atrial systole (measured electrocardiographically); ES = end-systole; F = termination of rapid filling.

the region of the myofibrillar contractile proteins[18] and produces actin-myosin dissociation. Laboratory and clinical studies indicate that the energy-dependent mechanisms responsible for this process are sensitive to low levels of ischemia[17–22] and to hypertrophy.[23–25] In addition to these inactivation-dependent mechanisms, LV relaxation is also influenced importantly by LV loading conditions,[26,27] including the rate and extent of coronary blood flow, regional LV nonuniformity or asynchrony, end-systolic pressure and end-systolic volume.[26–29] Any or all of these mechanisms may contribute to impaired relaxation in patients with HC.

Influence of calcium-channel blocking agents: Several studies have demonstrated that abnormal LV diastolic function in HC may be modified favorably by calcium-channel blocking agents. In the studies of Hanrath et al,[30] acute intravenous verapamil administration improved echocardiographic indexes of LV relaxation and filling, manifested by a decrease in the isovolumic relaxation period and an increase in the peak rate of LV posterior wall thinning. Using combined radionuclide and hemodynamic measurements, we have observed an improvement in LV relaxation and filling in a subset of patients with both obstructive and nonobstructive HC after acute intravenous verapamil;[31] the time constant of relaxation diminished and the peak rate of LV filling increased. In patients with such early diastolic changes, the LV diastolic pressure-volume curve was shifted downward and rightward, indicating an improvement in pressure-volume relations (Fig. 3). Indexes of LV diastolic function improved in these patients after acute verapamil administration despite evidence of a significant negative inotropic effect which, by itself, would be expected to cause further deterioration in LV diastolic performance. Similar improvement in LV diastolic pressure-volume relations after

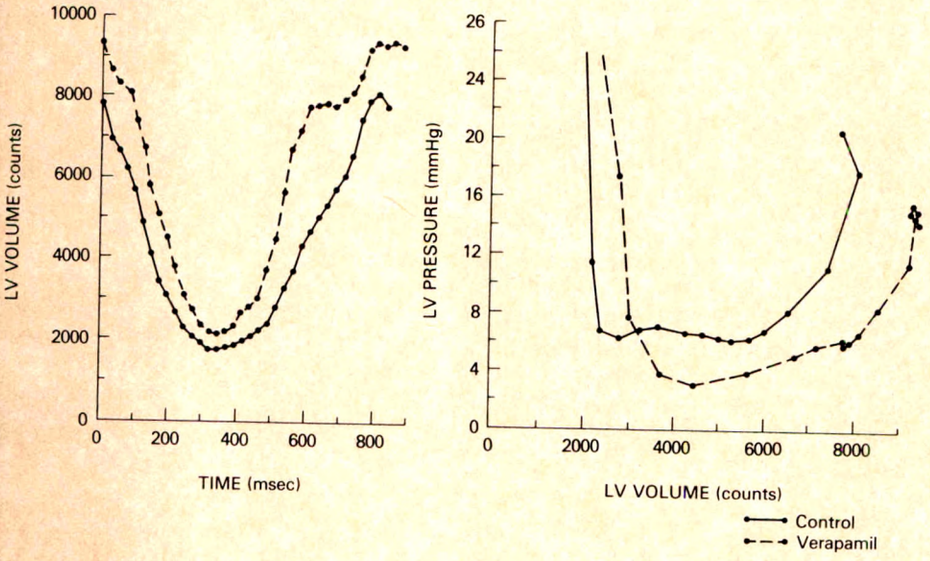

FIGURE 3. Effect of intravenous verapamil on left ventricular (LV) filling and diastolic pressure-volume relations obtained from combined radionuclide and hemodynamic measurements. In the volume curves (**left**), verapamil results in increased rate and extent of rapid filling, increase in stroke volume and reduced contribution of atrial systole. These changes are associated (**right**) with a downward and rightward shift in pressure-volume curve, indicating improved pressure-volume relations. Reprinted with permission from *Circulation*.[31]

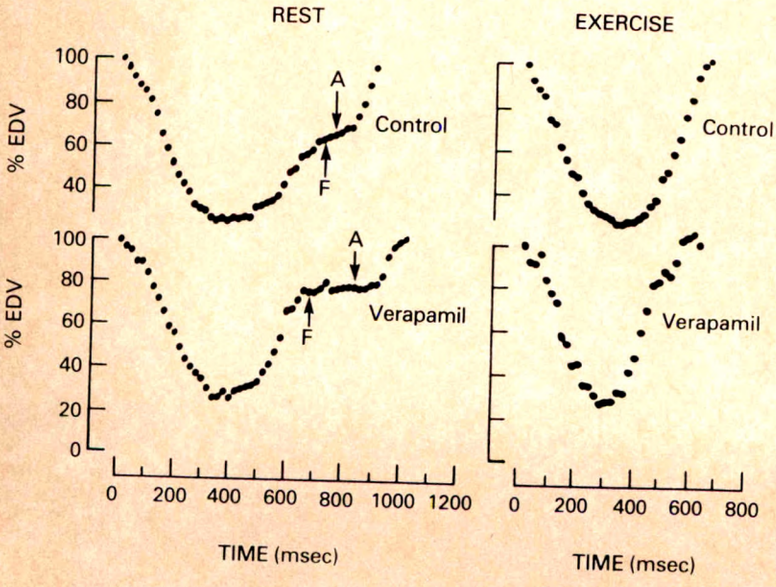

FIGURE 4. Left ventricular volume curves by radionuclide angiography at rest and during exercise in patient with hypertrophic cardiomyopathy. Oral verapamil (480 mg/day) results in enhanced diastolic filling at rest: shortened isovolumic phase, increased rate and extent of rapid diastolic filling and reduced contribution of atrial systole to total filling volume. Increased rate of filling is also evident during exercise. Each point represents 20 ms. EDV = end-diastolic volume.

erapamil administration have been reported by Chatterjee et al.[32] Improved LV relaxation, filling and diastolic pressure-volume relations have also been reported after the short-term administration of nifedipine in patients with nonobstructive HC by Lorell et al,[33] using combined hemodynamic-echocardiographic techniques, and by Senn et al,[34] using echocardiography.

Verapamil and nifedipine may improve indexes of LV relaxation and diastolic function in HC by direct effects on myocardial inactivation or by decreasing ischemia, increasing coronary blood flow or altering the loading conditions of the left ventricle. In this regard, Paulus et al[35] recently compared the relative effects of acute nitroprusside and nifedipine administration on LV relaxation, filling and distensibility in patients with nonobstructive HC. Despite similar decreases in systemic arterial pressure, nifedipine was associated with an increase in LV distensibility as well as less prolongation of LV isovolumic relaxation and less depression of peak LV filling rate compared with nitroprusside. These data suggest that nifedipine enhances LV diastolic performance independent of its vasodilatory properties.

Oral verapamil administration also improves LV diastolic filling, as assessed noninvasively by radionuclide angiography, during both short- and long-term therapy. With this technique, quantitative indexes of LV systolic and diastolic function are derived from analysis of LV time-activity curves, which represent relative changes in LV volume during the average cardiac cycle. In most patients with HC studied by this technique,[15,16] LV rapid diastolic filling is impaired, manifested by diminished peak filling rate, prolonged interval from end-systole to peak filling rate, reduced contribution of rapid diastolic filling to total LV stroke volume and increased contribution of atrial systole (Fig. 2). After 1 to 2 weeks of oral therapy (320 to 640 mg/day), verapamil does not affect indexes of LV contractile function but significantly alters indexes of diastolic filling at rest (Fig. 4): increased rate and extent of rapid diastolic filling, shortening of the period from end-systole to peak filling rate and reduced contribution of atrial systole to LV filling volume.[15,16] After 1 to 2 years of oral therapy, the improvement in LV diastolic filling is less marked than the initial short-term improvements.[36] However, when verapamil is withdrawn after 1 to 2 years, LV diastolic filling deteriorates, indicating a persistent reversible effect of the drug on LV diastolic function. In contrast, β blockers do not appear to affect LV diastolic performance in HC.[15,37]

Radionuclide angiographic studies performed during exercise[38] also demonstrate enhanced LV diastolic filling after verapamil (Fig. 4); similar improvement in diastolic indexes of LV function have been observed during exercise during oral nifedipine therapy.[38] These findings are consistent with the hemodynamic data from a study by Hanrath et al,[39] in which a decrease in LV filling pressures during exercise was measured after 7 weeks of oral verapamil administration. Hence, enhanced LV diastolic performance may account, at least in part, for the objective improvement in exercise tolerance frequently seen in patients during verapamil therapy.[40,41] In this regard, improved indexes of LV diastolic filling, measured at rest, correlate significantly with improvement in symptoms, both short-term (1 week to 1 month) and long-term (1 to 2 years).[42] During long-term studies, 80% of patients with a persistent increase in peak LV filling rate have persistent improvement in exercise tolerance relative to preverapamil values, compared with only 11% of patients in whom peak filling rate remains unchanged or decreased relative to preverapamil values. These data suggest that enhanced LV relaxation and filling are important mechanisms by which many patients with HC experience improvement in symptoms during treatment with verapamil.

Coronary Artery Disease

LV relaxation and distensibility: Abnormal LV diastolic performance is a common manifestation of CAD. As in HC, LV diastolic dysfunction in CAD arises from impaired LV relaxation, reduced LV distensibility or both. In patients with previous myocardial infarction, with or without diminished LV regional and global systolic function, diastolic dysfunction results primarily from myocardial fibrosis, with alterations in the distensibility characteristics of the left ventricle.[2,3,43–46] During periods of active ischemia, myocardial inactivation is inhibited, and LV relaxation is prolonged or incomplete, thereby altering LV filling characteristics and aggravating diastolic pressure-volume relations.[17,19,47–52] Hence, reversible decreases in LV distensibility may occur on the basis of impaired LV relaxation stemming from transient LV ischemia (Fig. 5). Impaired LV diastolic function may also occur under resting conditions in many patients with CAD in whom LV contractile function is normal and in whom there is no evidence of either previous myocardial infarction or active myocardial ischemia.[53–56] In many such patients, impaired LV filling under resting conditions improves after successful percutaneous transluminal coronary

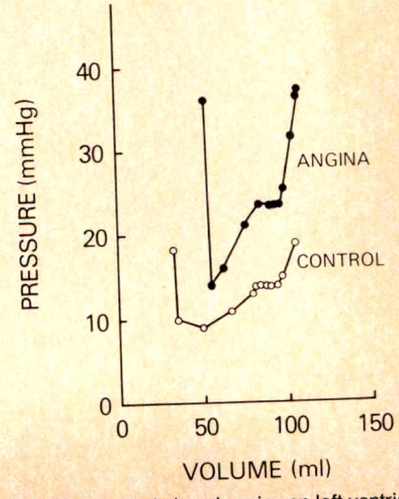

FIGURE 5. Effect of pacing-induced angina on left ventricular diastolic pressure-volume relation in coronary artery disease. Reprinted with permission from *Eur J Cardiol.*[52]

angioplasty,[57] with no concomitant change in resting heart rate or ejection fraction, suggesting that these diastolic abnormalities in CAD are not fixed but may be modified by the extent of reversible myocardial ischemia or reduced coronary flow. Moreover, recent data suggest that impaired diastolic filling in patients with normal systolic function is associated with asynchronous LV regional function, and that improved diastolic filling after percutaneous transluminal coronary angioplasty is associated with a reduction in regional asynchrony.[58]

Influence of calcium-channel blocking agents: Impaired LV filling in patients with CAD also improves after short-term oral verapamil therapy,[59] both at rest and during exercise-induced ischemia (Fig. 6). Similarly, Lorell et al[60] demonstrated improvement in LV relaxation and distensibility during pacing-induced ischemia in patients with CAD treated acutely with sublingual nifedipine. Enhanced LV diastolic function after administration of verapamil or nifedipine may, as with percutaneous transluminal coronary angioplasty, reflect alterations in the severity of reversible ischemia or the magnitude of coronary flow. Alternatively, these agents may have direct effects on myocardial metabolism and inactivation. In this regard, the data of Nayler and Williams[18] suggest that disturbances of intracellular calcium metabolism during myocardial ischemia may account, at least in part, for incomplete or impaired relaxation and altered diastolic tone. Impaired myocardial relaxation during hypoxia appears to be reversible under some experimental conditions and may be modified by intracellular calcium availability.[20,61] Lorell and Barry[62] demonstrated impaired relaxation in cultured chick embryo ventricular cells exposed to a high concentration of external calcium; this inhibition of relaxation was reversed by verapamil. Hence, impaired LV relaxation resulting from reduced myocardial inactivation during acute ischemia may possibly be improved by verapamil, nifedipine and other agents that reduce calcium ion flux across the myocardial membrane.

Enhanced diastolic performance of the intact left ventricle by calcium-channel blocking drugs may also arise from changes in LV loading conditions, such as blood pressure, heart rate and LV contractile function. Although it is impossible to separate completely the potential influence of altered LV loading conditions on verapamil- or nifedipine-induced improvement in LV relaxation and filling in the intact heart, recent data of Urquhart et al[63] suggest that verapamil may exert beneficial effects on LV diastolic function independently of changes in LV loading conditions. In these hemodynamic studies, dose-response curves to verapamil in dogs during acute ischemia indicated that the rate of LV diastolic filling increased before measurable changes in heart rate, left atrial pressure or systemic blood pressure were observed.

Although LV relaxation and filling in CAD are depressed by myocardial ischemia, these altered diastolic properties of the left ventricle may also potentiate ischemia and contribute to symptom production. For example, reduced LV relaxation with associated impairment in the rate and extent of LV diastolic filling and reduced LV distensibility may result in increase in LV filling pressures (Fig. 5) and symptoms of dyspnea frequently observed in patients with CAD during acute myocardial infarction or reversible ischemia. Moreover, reduction in the rate of decrease of early diastolic ventricular wall tension resulting from prolonged or in-

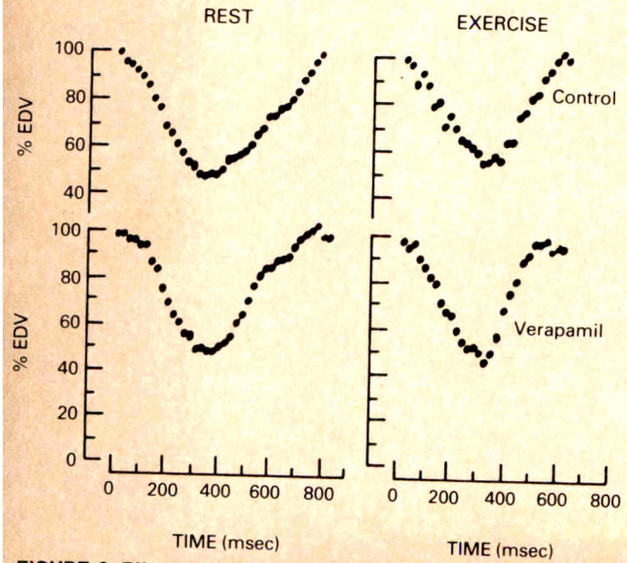

FIGURE 6. Effect of oral verapamil (480 mg/day) on left ventricular diastolic filling in patient with coronary artery disease. Radionuclide angiographic volume curves demonstrate increased rate of diastolic filling both at rest and during exercise. Each point represents 20 ms. EDV = end-diastolic volume.

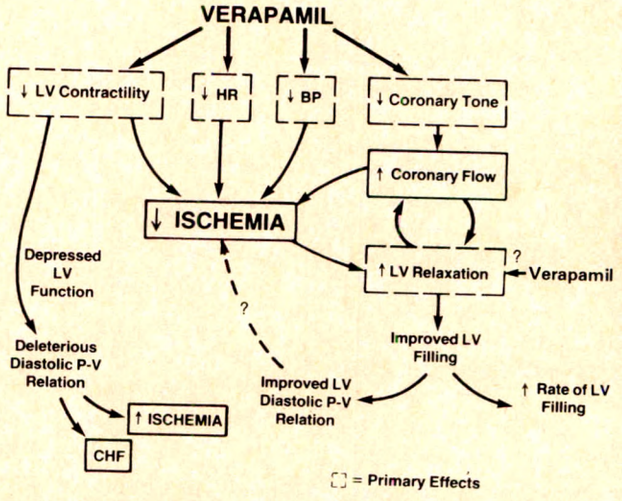

FIGURE 7. Mechanisms of verapamil effects in coronary artery disease. Primary actions include both a decrease in myocardial oxygen requirements (through decreases in left ventricular [LV] contractility, heart rate [HR], and blood pressure [BP]) and increase in coronary blood flow (through coronary artery dilatation and, possibly, enhanced left ventricular relaxation). Improved relaxation may also be a manifestation of decreased ischemia or altered loading conditions. Significant negative inotropic effects in isolated patients may lead to deleterious diastolic pressure-volume (P-V) relations, which may aggravate angina or precipitate symptoms of pulmonary congestion. Similar mechanisms apply to nifedipine, with exception of minimal primary effects on contractility and heart rate.

complete relaxation may impede regional anterograde and collateral coronary flow, and alterations in LV distensibility, with increased LV diastolic pressures, may aggravate end-diastolic wall stress and increase myocardial oxygen requirements. If these mechanisms are operative, LV diastolic dysfunction in CAD, as in HC, may contribute to the severity of symptoms; amelioration of these diastolic abnormalities by calcium-channel blockers may contribute to the improvement in symptoms in many patients during treatment with these agents. For these reasons, it is helpful to consider enhanced LV relaxation as a potential primary effect in the complex and interrelated mechanisms of action of the calcium-channel blockers in CAD (Fig. 7).

In conclusion, decreased LV distensibility and impaired LV relaxation are characteristic features of HC that result in impaired LV diastolic filling. These factors undoubtedly contribute to the pathophysiologic mechanisms leading to the development of symptoms in these patients. Impaired LV relaxation may play an analogous role in patients with CAD. Both verapamil and nifedipine favorably modify indexes of LV diastolic performance by way of a decrease in ischemia, salutary alteration in LV loading conditions or direct effects on myocardial inactivation. These actions suggest that enhanced LV diastolic function is an important primary or secondary mechanism contributing to the beneficial effects of these drugs in the hypertrophied or ischemic left ventricle.

Microvascular Spasm as a Cause of Cardiomyopathies and the Calcium-Blocking Agent Verapamil as Potential Primary Therapy

EDMUND H. SONNENBLICK, MD, FREDERICK FEIN, MD, JOSEPH M. CAPASSO, PhD, and STEPHEN M. FACTOR, MD

The origin of cardiomyopathies, a major cause of cardiac disability and death, has been largely unexplained. Pathologic features, common to all cardiomyopathies independent of origin, include ventricular hypertrophy and diffuse scarring with variable amounts of ventricular dilatation. This problem was studied experimentally in 2 models of congestive cardiomyopathy: the hereditary cardiomyopathic Syrian hamster and the hypertensive-diabetic rat. In both the genetic and the acquired disease models, there is focal myocytolytic necrosis followed by healing with focal scars, ventricular wall hypertrophy, ventricular dilatation with congestive heart failure and, ultimately, death. In view of the heterogeneous pathologic features of both diseases, silicone rubber perfusions have been used to study the microcirculation of the heart in these animals; microvascular spasm has been demonstrated early in the disease associated with small areas of myocytolytic necrosis that undergo subsequent fibrosis. Reactive hypertrophy then ensues as a compensatory response to this myocellular necrosis; it is the combination of cell loss and slowly decreasing contractility resulting from the reactive hypertrophy, which culminates in a cardiomyopathy. Administration of verapamil or prazosin to the cardiomyopathic Syrian hamster prevents microvascular spasm and development of cardiomyopathic changes in the myocardium. In view of these and other findings related to the anatomy and hyperreactivity of microcirculation, it is concluded that hypertrophic congestive cardiomyopathies may be caused by focal cell loss due to microvascular spasm and reperfusion injury, with the subsequent development of focal fibrosis and reactive hypertrophy in response to the myocardial necrosis. Myocytes in the cardiomyopathic heart may also be abnormal so that they are unable to tolerate transient focal ischemia without becoming necrotic. A suggestion is made that the ultimate therapy of cardiomyopathies may involve the early treatment of the microvascular spastic lesion in order to prevent further myocardial cell loss. Support of myocardial contractility and treatment of peripheral circulatory defects late in the process of this disease can then only be viewed as largely palliative.

(Am J Cardiol 1985;55:179B–184B)

The study and treatment of dilated, congestive cardiomyopathies has focused predominantly on the late stages of disease when clinical symptoms are already evident. Although the treatment of congestive heart failure has improved with the development of new inotropic agents and application of peripheral vasodilator therapy, these approaches are essentially palliative in that they do not appear to alter the underlying pathologic cause of failure, nor do they change the fatal outcome of the process. Thus, the pathogenesis of primary myocardial failure, which results in ventricular dysfunction, depressed cardiac pump performance and, ultimately, in clinically apparent congestive heart failure, remains unsolved. The fact that short- or long-term patient survival appears to be intimately associated with the extent of myocardial dysfunction regardless of its origin,[1] emphasizes the importance of preserving myocardial function if mortality rate is to be altered. In this report we review some recent data from our laboratories concerning the cause of myocardial failure in several different models of cardiomyopathy,

From the Departments of Medicine (Division of Cardiology) and Pathology, Albert Einstein College of Medicine, New York, New York. This study was supported in part by Grants HL-18824, HL-20426 and HL-23171 from the National Heart, Lung, and Blood Institutes, National Institutes of Health, Bethesda, Maryland.

which may be directly relevant to the treatment of the disease in man.

Components of Heart Failure

There are 2 components to the syndrome of heart failure. The first is myocardial failure, which is characterized by a decrease in the capacity of heart muscle to develop force and shorten normally with ultimate depression of pump function. Such myocardial failure is frequently associated with pressure overloads and resultant hypertrophy, or with either segmental or diffuse loss of myocardium, which is subsequently associated with variable amounts of reactive hypertrophy in response to the cell loss. Ventricular dilatation occurs as pump function decreases. In the congestive cardiomyopathies, ventricular failure is generally considered to result from diffuse myocellular dysfunction of unknown origin.

The second component is congestive heart failure, which is the systemic response to inadequate pump function, characterized by an inability to augment cardiac output to meet peripheral organ requirements. Sympathetic nervous system activity and renal vasoconstriction occur with activation of the renin-angiotensin system, leading to augmented peripheral vascular resistance, peripheral congestion and edema. The treatment modalities available in this syndrome are largely directed toward these peripheral factors. However, treatment that begins after pump failure does little to alter the significantly damaged myocardium except when a substantial pressure or volume overload can be removed. The question arises, however, if anything can be done to affect and arrest the process of myocardial failure before it becomes severe. In order to develop a rational approach for the treatment of cardiomyopathies, the mechanisms by which myocardial failure occurs in the absence of abnormal loading require definition.

The role of hypertrophy per se in producing myocardial failure remains at issue. Although hypertrophy resulting from renovascular hypertension leads to a slowing of myocardial contraction and relaxation,[2] these contractile changes are totally reversible within broad limits when the overload is removed. Thus, myocardial hypertrophy alone is not an adequate explanation for irreversible myocardial failure. Segmental myocardial necrosis associated with obstructive coronary vascular disease may also result in acute ventricular failure if sufficient muscle mass is lost;[3] this loss of myocardium creates an excess load for the noninfarcted portion of the heart, which leads to the development of compensatory or reactive hypertrophy.[4] In attempts to normalize the load for a fixed number of nonproliferating myocytes, the myocardial cell can only increase in mass, not number. If compensation is adequate, the heart may function normally for a considerable period of time. However, either progressive cell loss secondary to supervening ischemic events or the hypertrophic process itself, which can lead to myocellular contractile dysfunction,[5,6] may eventuate in myocardial failure even when further ischemia is absent. These alterations may then create a late-stage picture in ischemic heart disease of congestive myopathy. The process of segmental myocardial loss in acute myocardial infarction with subsequent compensatory hypertrophy as described earlier is relevant to the problem of "idiopathic," dilated, congestive cardiomyopathy. Although idiopathic cardiomyopathies have been considered the result of a diffuse process that affects the myocardial cells equally throughout the ventricle, the pathologic features are rather focal and nonspecific.[7–9] Typical findings in human congestive cardiomyopathy include a large heart, either firm or flabby, with prominent ventricular dilatation, and interstitial fibrosis with focal, discrete zones of myocytolytic necrosis leading to replacement scarring associated with variable degrees of myocellular hypertrophy of uninvolved muscle. None of these pathologic features is characteristic solely of cardiomyopathy. Similar alterations may also be seen in the hearts of patients with significant obstructive coronary artery disease.

Our interest in the pathologic features of cardiomyopathy was stimulated by the focal nature of the processes in the ventricular wall. Despite the generally accepted view that cardiomyopathies result from diffuse myocellular disease, the absence of diffuse pathologic abnormalities, at least in the early stages, suggests that there may be focal events affecting discrete, small volumes of tissue accounting for the myocardial degeneration. Studies of several experimental models have enabled us to pinpoint these focal events.

Experimental Studies of Cardiomyopathies

We have studied 2 distinct models of cardiomyopathy in animals that are characterized by degenerative myocardial lesions similar to those observed in human cardiomyopathies. The hearts of Syrian hamsters[10–12] with hereditary cardiomyopathy and rats with combined hypertension and diabetes[13–15] have shown regions of focal fibrosis and myocytolysis associated with hypertrophied but otherwise normal-appearing muscle.

The Syrian hamster provides a unique genetic model of a cardiomyopathy. Focal myocardial necrosis begins as early as 1 month of age, leading to congestive heart failure within a year. The pathogenesis of the myocytolytic necrosis characteristic of the problem is unknown, but it has been suggested that there is increased calcium flux across the sarcolemma, leading to cellular hypercontraction, mitochondrial calcification and cell death.[16,17] These observations would suggest that there is a diffuse and probably uniform cellular abnormality. Why then should the pathologic features be focal in nature? Although the possibility that these focal necrotizing lesions are mediated by abnormalities of the microcirculation has been considered, no significant changes have been observed in these vessels when routine histologic methods were used.

To evaluate the role of the microvasculature in the cardiomyopathy of the Syrian hamster, a series of perfusions with silicone rubber solutions were performed in living animals.[12] This material perfuses the entire microcirculation; after tissue clearing, the microvasculature can be visualized in intact myocardium in a 3-dimensional array. Studies of such cleared specimens in cardiomyopathic hamsters at different stages of the

disease reveal frequent areas of microvascular constriction, diffuse narrowing and luminal irregularity (Fig. 1), strikingly similar to vascular spasm observed in larger vessels during angiography.[12] Areas of severe focal constriction in small arterioles were often seen proximal to the necrotic and scarred myocardium rather than within these areas per se in the late stages of disease (90 to 150 days). In earlier stages (30 to 50 days), before development of extensive necrosis, the spastic changes were also observed, suggesting that spasm was a cause rather than an effect of the necrotizing process. Routine sectioning of nonperfused hearts failed to reveal fixed structural lesions in the small myocardial vessels, and direct histologic visualization of vessels with marked hyperreactivity demonstrated that the luminal narrowing was not the consequence of anatomic lesions in the microcirculation. Thus, although structural lesions in these vessels could produce the same appearance with silicone rubber microangiography, the absence of vessel wall pathologic features supports the view that these lesions represent a dynamic process consistent with microvascular spasm.

Further evidence that microvascular hyperreactivity contributes significantly to myocardial degeneration in the cardiomyopathy of the Syrian hamster comes from studies with the "slow-channel" calcium-blocking agent and coronary vasodilator verapamil. Significantly, pretreatment of young hamsters with 0.5 mg of verapamil twice a day (bid) subcutaneously before development of focal myocardial necrosis (30 to 50 days) abolishes the microvascular spasm[12] and prevents myocytolytic lesions. Recent studies showing prevention of vascular lesions using the α-adrenergic blocking agent prazosin (6 to 8 mg/kg bid subcutaneously) provide further evidence that the microvasculature in the hamster heart undergoes spasm leading to focal myocardial necrosis.[18] Prazosin markedly diminished the frequency of spasm in precapillary arterioles, and there was a highly significant decrease in myocardial necrosis in the treated versus the untreated cardiomyopathic animals (0.66 versus 8.80% of ventricular area necrotic, respectively). The promising results with verapamil and prazosin must still be viewed with caution, because, to date, we have prevented microvascular spasm and myocytolytic necrosis only during the early stages of active necrosis (30 to 50 days), and have yet to treat animals in the hypertrophic (150 to 250 days) or the congestive (250 to 350 days) stages with these drugs.

Based on these preliminary results, however, we have tentatively concluded that in the cardiomyopathic hamster, focal, transient spasm of small blood vessels causes myocytolytic necrosis leading to scar formation and reactive hypertrophy, which eventuates in the cardiomyopathy. This does not exclude the possibility that the myocytes may also be abnormal,[16,17] which may make them susceptible to infarction during the ischemia induced by the episodic microvascular spasm. Indeed it is possible that a defect in cell surface function that fails to exclude calcium from the cell may produce both vascular spasm and a tendency for reperfusion type myocardial cell necrosis in the areas subserved by the spastic small vessels.

Studies of the hypertensive diabetic rat,[13] an experimental model of an acquired disease initially described in humans,[19] reveal morphologic features similar to other forms of cardiomyopathy. When diabetes is induced in rats by streptozotocin, abnormalities of myocardial contraction occur characterized by slowing of contraction and delayed relaxation.[20] It is noteworthy that no histologic alterations occur, and all of the functional abnormalities are reversed by the administration of insulin.[21] Similarly, when renal hypertension is produced in rats, ventricular hypertrophy occurs with contractile abnormalities similar to those described in the diabetic rat. Again, these changes are all reversible when the hypertension is reversed and the hypertrophy resolves.[22]

However, when experimental 1-clip, 2-kidney renovascular hypertension is superimposed on streptozotocin-induced diabetes, major pathologic changes occur

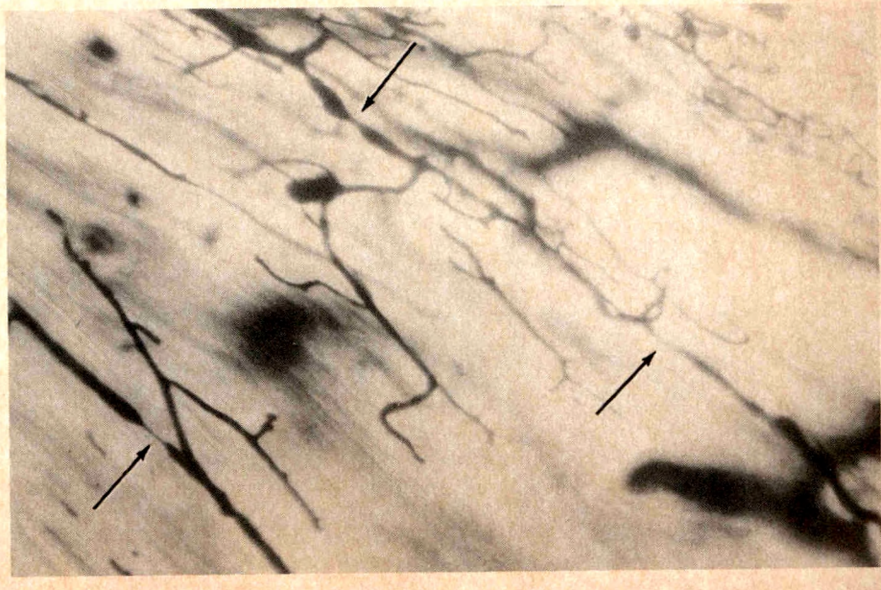

FIGURE 1. Silicone rubber-perfused region of cleared myocardium from 44-day-old cardiomyopathic Syrian hamster. Note numerous focal constrictions (**arrows**) in arteriolar-sized vessels in this field, which are consistent with microvascular spasm. Although fixed structural lesions in these vessels could produce same appearance, no such lesions were demonstrated in routine sections. Furthermore, pretreatment of these animals with verapamil abolished spasm and prevented development of myocardial necrosis (magnification ×155).

with myocytolytic necrosis, replacement fibrosis and myocellular hypertrophy, similar to those seen in the cardiomyopathic hamster. In this model, streptozotocin was injected 1 week after left renal artery stenosis was produced in young female Wistar rats. In addition to the replacement fibrosis typical of hamster cardiomyopathy, there is also extensive interstitial deposition of collagen and basement membrane material around blood vessels and hypertrophied myocardial cells. Studies of the microcirculation in this model with in vivo silicone rubber perfusions have revealed numerous microvascular constrictions, tortuosities and microaneurysms.[14,15] Semiquantitative analysis of these microvascular abnormalities in hypertensive-diabetic animals after 8 weeks of combined hypertension and diabetes revealed a highly significant increase of lesions when compared with normal control subjects and normotensive diabetic animals.[15] Nondiabetic hypertensive animals had an intermediate number of vascular lesions, consistent with the intermediate degree of myocardial degeneration we have shown previously.[13] The vascular abnormalities, which are similar to those we described in the cardiomyopathic hamster heart, may account for the extensive myocytolytic myocardial necrosis. The interstitial scarring, however, may be secondary to increased microvascular permeability related to both the diabetic state and the hypertension. The combination of these 2 vascular insults may lead to accelerated leakage of fluid into the interstitial space. Williamson and Kilo[23] proposed that extravascular plasma constituents might stimulate synthesis of basement membrane material and collagen in diabetes, leading to such fibrosis. In addition, studies of ventricular papillary muscles isolated from animals that were both hypertensive and diabetic for 4 to 5 months revealed profound electrophysiologic and mechanical changes, which were more severe than in animals with isolated diabetes or hypertension.[24,25] A high mortality rate (55%) was observed over a 7-month period of observation and postmortem studies revealed a high frequency of acute and chronic pulmonary and hepatic congestion.[26]

Overall, the focal nature of the lesions in this disease strongly suggests that the microcirculation mediates myocellular necrosis and interstitial collagen deposition. Both processes could cause myocardial dysfunction by limiting the number of myocardial units available for contraction, by stimulating the development of hypertrophied muscle in unaffected zones and by stiffening the ventricle through interstitial scarring, which may lead to diminished diastolic compliance.

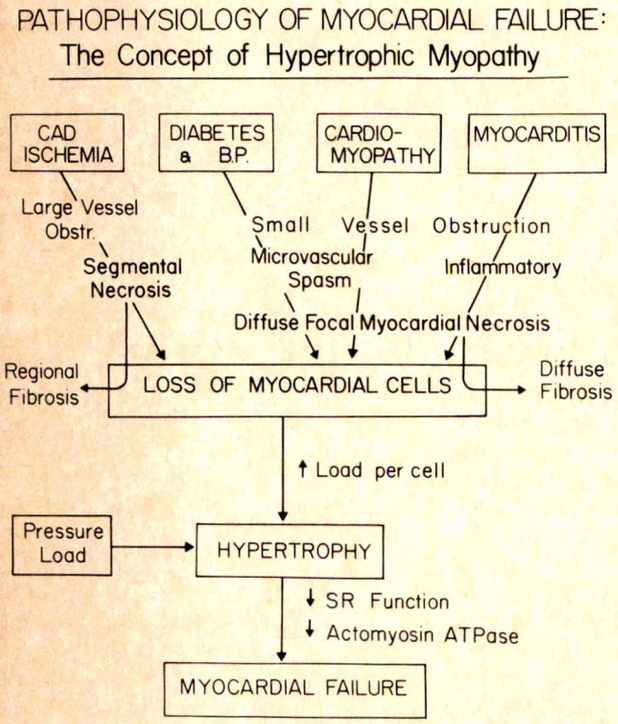

FIGURE 2. Our conceptual view of myocardial failure. Many different processes, including ischemic coronary artery disease (CAD), diabetes mellitus and hypertension (BP), some forms of cardiomyopathy including that seen in the hamster and myocarditis, may lead to loss of myocardial cells. This cell loss can develop from large-vessel obstruction producing segmental necrosis, as in acute myocardial infarction, microvascular spasm causing focal necrosis and inflammatory processes of unknown nature that may affect microcirculation or myocardial cells directly. Resultant loss of myocytes increases the load per cell, stimulating hypertrophy of unaffected myocardium. End-stage of myocardial failure results from inadequate numbers of cells to pump effectively, stiffening of myocardium due to connective tissue deposition and decreased function associated with pathologic cellular hypertrophy. Although myocardial failure may occur rapidly with myocardial infarction, in cardiomyopathy these processes may take years to develop and they may not be clinically apparent until patient presents with congestive heart failure. ATPase = adenosine triphosphatase; SR = sarcoplasmic reticulum.

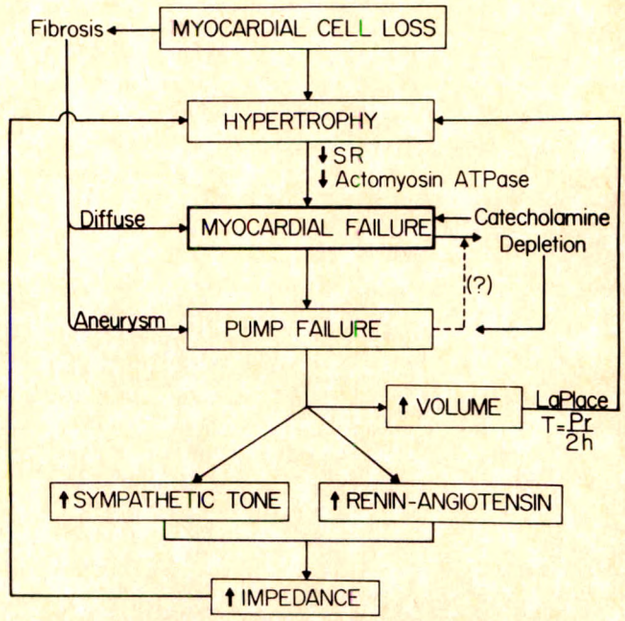

FIGURE 3. Interrelations between myocardial cell loss and pump failure. Myocardial cell loss leads to both reactive hypertrophy and myocardial failure. Ultimately, pump failure ensues, which initiates compensatory responses that feed back to create secondary overloads and more hypertrophy and failure. This secondary impedance increase as well as volume overload may extend initial pump dysfunction. ATPase = adenosine triphosphatase; H = radius; P = pressure; SR = sarcoplasmic reticulum; T = tension.

Our studies of the Syrian hamster and the hypertensive-diabetic rat with cardiomyopathies suggest that microvascular spasm plays a significant role in the development of myocardial degeneration and failure. However, a crucial question remains: can transient obstruction of the microcirculation cause small areas of discrete myocardial necrosis? A hypothetic requirement for this process to occur is for the microcirculation to be organized into an end-vessel system. If capillaries were diffusely interconnected by anastomoses, then localized microvascular obstruction would not be likely to produce necrosis of small volumes of tissue. Recent studies in our laboratory have, in fact, shown that the cardiac microcirculation is arranged into end-capillary loops without intercapillary connections in the dog[27] and human,[28] and we have reason to believe that a similar pattern exists in rodents (unpublished observations, 1981). We also have demonstrated that embolization of 25 or 50 μm microspheres into the coronary microcirculation of dogs and rats leads to focal myocytolytic necrosis very similar to what we described in the cardiomyopathic hamster and the hypertensive-diabetic rat.[29] Variation in the size of necrotic lesions may depend on the size of the vessel occluded, because 50 μm microspheres produced larger lesions than 25 μm beads. Variably sized necrotic lesions in clinical and experimental diseases may be explained by similar mechanisms. An interesting observation from our experimental models of cardiomyopathy is that necrosis developing secondary to microembolization appears to be due to vasospasm. Pretreatment of animals with phentolamine (an α-adrenergic blocking agent) before embolization prevented necrosis in the dog, suggesting that anatomic obstruction of the microvasculature by beads alone was not the cause of tissue necrosis.[29]

In summary, our recent investigations reveal that microvascular spasm is present in the cardiomyopathic Syrian hamster, the hypertensive-diabetic rat and the myocardial microcirculation of the dog and rat embolized with microspheres. In the models of congestive cardiomyopathy, it appears that microvascular spasm leads to focal cell necrosis and subsequent myocardial scarring. From these varied observations we have speculated that such microcirculatory events are a general feature of congestive cardiomyopathy. If so, microvascular lesions may explain not only the pathologic features of cardiomyopathy, but also the occasional presence of atypical angina-like chest pain in patients in whom the large coronary arteries are normal.

It appears then that there are many common features in congestive cardiomyopathy as well as in ischemic congestive heart failure associated with obstructed coronary arteries. These similarities are summarized in Figure 2. Microvascular spasm in cardiomyopathy producing focal myocardial necrosis, obstructive coronary artery disease causing segmental myocardial necrosis and, possibly, inflammatory myocarditis leading to loss of myocardial cells will all eventuate in a decreased number of nonproliferating myocytes. This cell loss increases the load borne by the remaining unaffected myocytes, leading to their compensatory hypertrophy. Subsequently, with extensive focal scarring and interstitial fibrosis, a threshold number of cells may be lost and compensation is no longer adequate. In addition, both replacement and interstitial fibrosis may limit overall ventricular compliance. Ventricular dilatation may supervene in an attempt to compensate for decreased myocardial function. Thus, what began as widespread focal and even clinically silent necrosis possibly secondary to microvascular spasm may terminate as a typical dilated and hypertrophied heart, ultimately causing congestive heart failure (Fig. 2 and 3).

One may speculate that microvascular spasm producing transient focal ischemia may result in reversible chest pain without persistent damage in the otherwise normal heart. When myocytes are abnormal with decreased ability to handle calcium loads,[17] similar transient focal ischemia may eventuate in a cardiomyopathy. Recent evidence of sarcolemmal defects in the Syrian hamster[30] raise the possibility that membrane abnormalities make the myocytes particularly susceptible to intermittent ischemia. In the hypertensive-diabetic rat, there may also be membrane alterations secondary to the diabetes, which, with the microvascular spasm associated with hypertension, may lead to accelerated focal myocardial abnormalities, with microvascular spasm mediating necrosis of cells that are unable to withstand transient ischemia.

If this concept of microvascular hyperreactivity is proven correct, it will provide an explanation for the heterogeneous pathologic features of congestive cardiomyopathy, and the paucity of alterations in the unaffected hypertrophied myocardial cells. Moreover, this hypothesis raises the possibility that understanding the pathogenesis of cardiomyopathy will allow specific drug therapy to be designed to prevent the progression of the disease process, even if the underlying myocellular defects cannot be treated. To date, therapy for congestive cardiomyopathy has been palliative and has used digitalis glycosides, catecholamines, vasodilators and diuretics, which in combination can increase myocardial contractility to improve ventricular performance and relieve pulmonary and systemic congestion. However, these agents do not halt the progression of the disease, and, in the case of inotropic agents, might actually increase the loss of myocardial cells secondary to microvascular spasm by enhancing calcium overloading of cells. Thus, it is not surprising that such therapy can improve symptoms without altering the fatal outcome of the disease process. In contrast, verapamil completely prevents myocardial necrosis and fibrosis and possibly the ultimate development of ventricular failure in the Syrian hamster. We hope that, in the future, treatment modalities that may affect the long-term prognosis will be designed for patients in the early stages of congestive cardiomyopathy. The findings presented here suggest that such a controlled therapeutic trial is currently warranted in man with enhanced survival being the clear and definitive endpoint to efficacy.

Acknowledgment: We appreciate the invaluable assistance of numerous investigators who contributed to these studies over the years. We thank Terry Moccia for excellent work in the preparation of the manuscript.

Use of Calcium-Channel Blocking Drugs in Hypertrophic Cardiomyopathy

DOUGLAS R. ROSING, MD, ULLA IDÄNPÄÄN-HEIKKILÄ, MD, BARRY J. MARON, MD, ROBERT O. BONOW, MD, and STEPHEN E. EPSTEIN, MD

Verapamil exerts a wide spectrum of hemodynamic effects in patients with hypertrophic cardiomyopathy (HC), and its administration offers an important alternative to β-receptor blocker therapy in such patients. The intravenous administration of verapamil to 62 patients in the catheterization laboratory decreased systolic blood pressure from 118 ± 17 to 102 ± 17 mm Hg ($p < 0.001$). It had no significant effect on heart rate, mean pulmonary artery wedge pressure, left ventricular (LV) end-diastolic pressure or cardiac output; however, LV outflow gradient in the basal state decreased from 62 ± 34 to 29 ± 34 mm Hg ($p < 0.05$). These findings demonstrate a decrease in LV outflow tract obstruction. Radionuclide angiography indicated the major action responsible for the reduction in obstruction appears to be an improvement in LV diastolic function. Short-term nifedipine administration to patients with HC produced no significant effect on LV outflow tract gradients and early diastolic filling. Short-term double-blind studies showed that verapamil improved exercise time by 26 ± 35% ($p < 0.005$) compared with placebo, whereas propranolol improved it by 21 ± 35% ($p < 0.025$). In a separate study, verapamil improved exercise duration by 38 ± 58% ($p = 0.02$) compared with placebo, whereas nifedipine improved it by 20 ± 47% (difference is not significant). Verapamil resulted in a more beneficial subjective symptomatic response than propranolol or nifedipine when compared with placebo. Long-term verapamil therapy was instituted in 227 patients; 133 of these patients have continued taking the medication for an average of 25 ± 13 months because their quality of life improved compared with what they experienced with their former therapy (usually β blocker). Improved exercise capacity of 40% has been maintained in 32 patients for 2 years. A decrease in ventricular septal thickness of 1.5 ± 2.6 mm was also found in 32 patients studied after 39 ± 8 months of verapamil therapy. Nine patients died during follow-up study, but it is unclear whether the drug increased survival or, conversely, whether any of the deaths could be attributed to verapamil administration. Significant adverse electrophysiologic and hemodynamic effects were seen in 59 instances. The electrophysiologic events, atrioventricular block and sinus arrest, were definitely verapamil-related, but it is uncertain how many of the hemodynamic problems of hypotension and pulmonary congestion were drug-related. It was necessary to discontinue verapamil in only 7% of patients because of adverse effects. These studies indicate that verapamil offers an important alternative to β-blocker therapy in selected patients with HC.

(Am J Cardiol 1985;55:185B–195B)

Until recently, the primary pharmacologic therapy for treating patients with hypertrophic cardiomyopathy (HC) was the administration of β-adrenergic receptor blocking agents.[1–3] Although β-blocker therapy is often effective in improving symptoms, not all patients benefit by the use of this group of drugs and many patients have undesirable adverse effects from these agents. Operative intervention, usually ventricular septal myectomy,[4] but occasionally mitral valve replacement,[5] offers an additional therapeutic approach. However, patients without significant left ventricular (LV) outflow tract obstruction are not candidates for operation. Furthermore, the intra- and early postoperative mortality rate for septal myectomy is 5 to 10%, and about 25% of patients do not receive satisfactory relief of symptoms during long-term postoperative follow-up study. As a result of these considerations, we began an intensive search for an alternative medical therapy for patients with this condition in 1977.

Because enhanced systolic function,[6] often leading to LV outflow tract obstruction,[7] and impaired diastolic function[6,8] are the characteristic hemodynamic features of patients with HC, it seemed to us that agents that decreased myocardial uptake of calcium might be helpful in improving these functional abnormalities. Kaltenbach et al's report[9] of symptomatic improvement in some patients with HC with the administration of the calcium antagonist verapamil provided further support for this approach. Because verapamil had been in general clinical use for 15 years, in 1977 we began administering this agent to our patients with HC. The primary purpose of this article is to review the experience with verapamil, as well as nifedipine, in treating patients with HC.

Hemodynamic Studies

Verapamil: Sixty-two patients received intravenous verapamil infusions at the time of cardiac catheterization performed after all cardiac medication had been discontinued for at least 5 half-lives. The mean age of the group was 44 years (range 21 to 70); 32 of the patients were men and 30 women. Thirteen patients had the nonobstructive form of the disease (basal or provokable LV outflow tract gradient ≤30 mm Hg). No patient had known significant coronary artery disease at the time of study. One patient was in atrial fibrillation and one had a demand ventricular pacemaker (VVI) in place. The remainder of the patients were in normal sinus rhythm at the time of study.

The effects of 10-minute drug infusions, at varying doses, on heart rate, systolic blood pressure, mean pulmonary artery wedge pressure, LV end-diastolic pressure, cardiac index and basal and provokable LV outflow tract gradients are shown in Tables I and II. Five patients had a verapamil-induced decrease in systolic blood pressure of ≥30 mm Hg and 2 of these patients had an increase in their basal gradients. No other patient had an increase in the gradient with verapamil administration. The effect of verapamil on outflow tract gradients was similar, independent of whether the gradient was provoked with a Valsalva maneuver, amyl nitrate inhalation or isoproterenol infusion. Twelve patients had a mean pulmonary artery wedge pressure >20 mm Hg at the time of control measurement. Figure 1 shows that verapamil administration produced a decrease in wedge pressure >2 mm Hg in 6 patients, resulted in no change (within ± 2 mm Hg) in 4, and caused a >2 mm Hg increase in 2. In 1 patient wedge pressure increased from 21 to 31 mm Hg

TABLE III Effects of Sublingual Nifedipine on Hemodynamic Features in 27 Patients

	HR (beats/min)	SBP (mm Hg)	PCW (mm Hg)	CI (L/min/M^2)	GRAD (mm Hg)	LVDV
C	78 ± 13	126 ± 15	15 ± 3	2.9 ± 0.8	56 ± 37	100%
N	91 ± 13*	103 ± 13*	17 ± 9	3.5 ± 0.8*	65 ± 43	131 ± 33%*

C = control; GRAD = basal subaortic left ventricular outflow tract gradient; HR = heart rate; LVDV = left ventricular end-diastolic volume; N = nifedipine; PCW = mean pulmonary artery wedge pressure; SBP = systolic blood pressure.
* $p < 0.005$.

and in another from 27 to 32 mm Hg. In 5 of 43 patients with a control mean pulmonary artery wedge pressure <20 mm Hg, verapamil resulted in an increase in pressure to >20 mm Hg (to 21, 22, 23, 24 and 35 mm Hg). Similar trends were observed in LV end-diastolic pressures.

In another article in this issue,[10] the effects of oral and intravenous verapamil administration on systolic and diastolic function, as measured by radionuclide angiography, are described in detail. Verapamil administration improved peak LV filling rate, time to peak filling rate, T time (time constant of LV pressure decrease after peak negative first derivative of LV pressure [dP/dt]), pressure-volume relation and contribution of rapid diastolic filling to overall LV filling. The LV ejection fraction decreased in response to intravenous verapamil but was unchanged when patients received it in short-term oral administration. Other investigators have found similar hemodynamic results with verapamil administration to patients with hypertrophic cardiomyopathy.[11–14]

Nifedipine: The hemodynamic effects of nifedipine administration resulted in a somewhat different trend compared with verapamil. Table III summarizes the effects of the short-term sublingual administration of 10 to 30 mg of nifedipine to 27 patients with no known coronary artery disease. Although the subaortic LV gradient did not decrease with nifedipine as it did with verapamil, there was an increase in cardiac output. The lack of change in gradient at a time when flow increased indicates that some decrease in LV outflow tract obstruction occurred. This effect may have been mediated by the increase in LV end-diastolic volume we observed,[15] although the mechanism by which diastolic filling increased is not clear. We found nifedipine exerted no effect on early diastolic filling, when measured by radionuclide angiography, during short-term oral administration (Table IV).[15] Filling improved when the same patients received oral verapamil; peak filling rate increased and time to peak filling rate decreased significantly when compared with the control situation (Table IV).

There is little additional information regarding the hemodynamic effects of nifedipine administration to patients with this disease. Lorell et al[16] observed that nifedipine administration improved diastolic function in a group of 10 patients, as did Senn et al[17] in a group of nonobstructive patients. Even less information is available regarding diltiazem administration to patients with HC. The only reported studies, by Nagao et al,[18,19] demonstrated that intravenous diltiazem decreased isovolumic LV relaxation time and bicycle exercise-

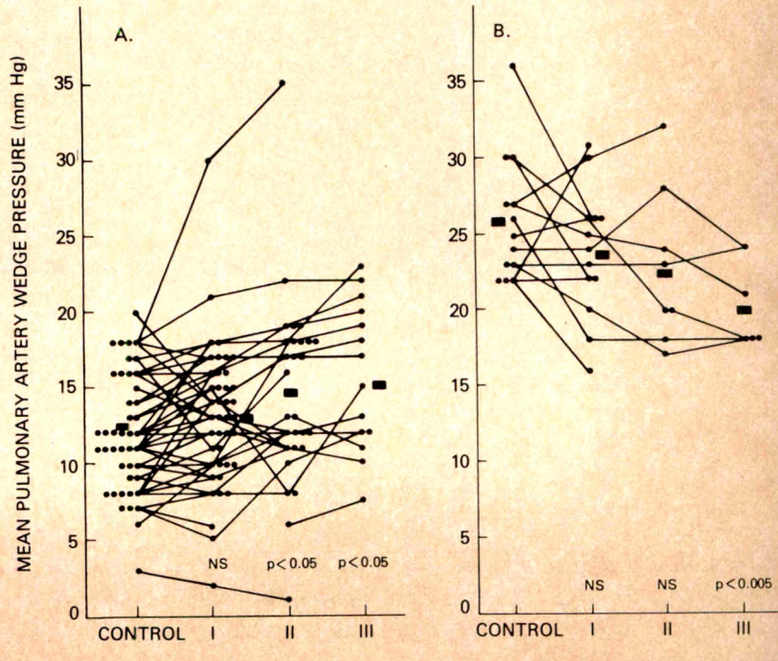

FIGURE 1. Response of mean pulmonary artery wedge pressure to verapamil infusions. Dose I = 0.007 mg/kg/min; II = 0.014 mg/kg/min; III = 0.021 mg/kg/min. Patients whose mean wedge pressures preverapamil were ≤20 mm Hg are displayed on **left,** and those whose preverapamil mean wedge pressures were >20 mm Hg are shown on **right. Horizontal bars** depict mean values for the group. P values represent comparisons with control values. F ratio for the left panel = 2.38 ($p = 0.07$), for the right panel = 2.98 ($p = 0.04$).

TABLE IV Nifedipine and Verapamil Effects on Left Ventricular Diastolic Function in 11 Patients

	PFR (EDV/s)	TPFR (ms)	HR (beats/min)	LVEF (c/o)
Control	3.2 ± 1.3	196 ± 32	77 ± 13	73 ± 11
Nifedipine	3.2 ± 1.1	192 ± 38	76 ± 11	71 ± 10
Verapamil	3.9 ± 1.2*	174 ± 32†	68 ± 8‡	72 ± 11

EDV = LV end-diastolic volumes; LVEF = LV ejection fraction; PFR = peak LV filling rate; TPFR = time to peak filling rate.
* $p < 0.02$ relative to control.
† $p < 0.05$ relative to control.
‡ $p < 0.002$ relative to control and nifedipine.

induced increases in pulmonary artery diastolic pressure.

Conclusion: The results of the hemodynamic studies indicate that intravenous verapamil, administered to patients with the obstructive form of HC, is capable of reducing LV outflow tract obstruction, as demonstrated by a decrease in LV outflow tract gradient with maintenance of cardiac output. The mechanism of this action appears to be both a decrease in systolic function, as shown by a decrease in the ejection fraction, and an increase in LV volumes produced by an enhancement of LV diastolic filling.[10] Although we have no data regarding the effect of long-term oral verapamil therapy on LV outflow tract obstruction, the work of Kaltenbach et al[20] would suggest that the oral administration of the drug also decreases LV outflow obstruction, and increases LV end-diastolic volume (10%) and stroke volume (11%). A preliminary report by Raff et al[21] described a 28% increase in LV end-diastolic volume without a significant change in end-diastolic pressure. We have demonstrated that after 1 year of verapamil therapy, the improvement in early diastolic function continues and, as in the short-term oral studies, the group as a whole still had no change in systolic function indexes.[10] However, the LV ejection fraction exhibited a persistent decrease (>5%) in individual patients. Kaltenbach et al[20] have also described a persistent negative inotropic effect (increased end-systolic volume and reduced peak LV systolic pressure) in 6 of 10 patients receiving long-term therapy.

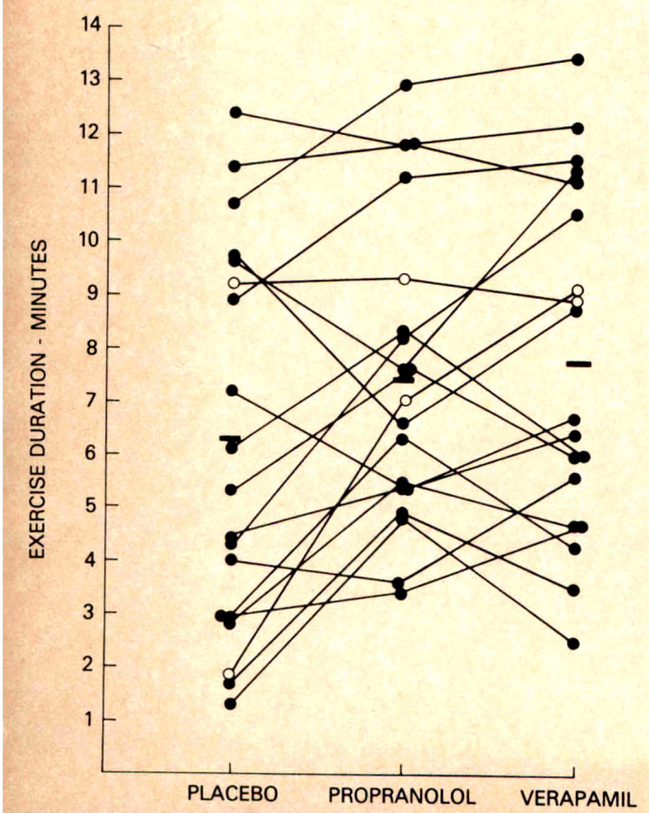

FIGURE 2. Effect of propranolol and verapamil administration on exercise capacity. **Horizontal bars** indicate mean values. **Closed circles** represent patients with obstructive hypertrophic cardiomyopathy; **open circles,** patients with nonobstructive disease. Reprinted with permission of American Heart Association.[22]

Thus, it would appear that the beneficial effects of the intravenous administration of verapamil to patients with HC result from a depression of systolic function and an enhancement of diastolic function. The salutory effects of long-term oral administration of the drug seem to be derived primarily from improved diastolic function with individual patients benefitting from decreased systolic function.

In the group of patients to whom we administered nifedipine, we could not demonstrate any consistent change in LV gradient or diastolic function. Although an increase in the calculated LV outflow tract orifice area may have occurred, LV systolic pressure remained increased, indicating that no decrease in LV wall stress occurred. Although our group data showed no hemodynamic benefit from nifedipine, there were isolated examples of significant decrease in LV outflow tract gradients and improvement in diastolic function. Moreover, Lorell,[16] Senn,[17] and their co-workers have described improved diastolic function in small groups of patients with the short-term administration of the drug.

Most of the foregoing descriptions and conclusions emphasize the effects of the calcium-channel blocking drugs in patients with the obstructive form of HC. However, the effects on filling pressures and diastolic function in subgroups of patients with nonobstructive disease or no basal LV outflow gradients appear to be the same.

Short-Term Studies

Verapamil-propranolol-placebo: Treadmill exercise capacity and symptomatic status were evaluated

in 19 patients,[22] 17 of whom were New York Heart Association functional class III, despite taking what was considered to be optimal medical therapy. No patient had known significant coronary artery disease at the time of study. The other 2 patients were functional class II. Fifteen patients were taking propranolol at the time of admission to the study (median dose 320 mg/day), and 4 had been receiving the drug but had discontinued it. Verapamil, propranolol and placebo were administered in a double-blind randomized fashion.

Exercise capacity is depicted in Figure 2. With placebo, the average exercise duration was 6.1 ± 3.5 minutes. With verapamil, the average exercise time increased by 26 ± 35% (1.6 ± 2.2 minutes, $p < 0.005$), and with propranolol, it improved 21 ± 35% (1.3 ± 2.2 minutes, $p < 0.025$). There was no significant difference between the results with propranolol and verapamil.

Patients were also asked to identify the drug period during which they felt "best" and "worst," and 16 of the 19 patients were able to do this, sometimes selecting more than 1 period as "best" or "worst." With placebo, 7 patients felt "best" and 7 "worst," with verapamil it was 9 "best" and 4 "worst," and with propranolol 3 "best" and 7 "worst." Patient assessment of symptomatic response agreed with the results of exercise testing in 9 of 16 patients.

Verapamil-nifedipine-placebo: In a similar short-term, randomized, double-blind crossover study[23] comparing the exercise and subjective symptomatic responses of 27 patients with HC and no known coronary artery disease with 5 days each of placebo, verapamil and nifedipine treatment, we found that with placebo, maximal exercise capacity was 5.5 ± 3.3 minutes. With nifedipine there was a tendency for improvement as exercise time increased by 20 ± 47% to 6.6 ± 2.8 minutes ($p = 0.11$), whereas with verapamil a significant prolongation of exercise time, 38 ± 58%, compared with placebo, to 7.7 ± 3.3 minutes ($p = 0.02$) occurred.

In addition, 13 patients described their symptomatic response as "best" with verapamil, whereas 7 did the same for placebo, and 6 for nifedipine (a patient could choose more than 1 drug period as "best" or "worst"). Only 4 patients stated they felt "worst" with verapamil, compared with 7 for nifedipine and 12 for placebo. Four patients were removed from the study because of adverse "drug effects" (hypotension in 1 patient while taking verapamil and in 1 patient taking placebo, and syncope and pulmonary edema in 1 patient each while taking nifedipine).

Long-Term Clinical Effects

Subjective responses: Oral verapamil therapy was evaluated in 227 patients from September 1977 to June 1982. Thirteen patients had been taking verapamil therapy for 2 to 11 months when first evaluated by us. Six patients received 2 trials of verapamil therapy (in 4, before and after ventricular septal myectomy, in 2, before and after other medical therapy). The age range was 7 to 76 years (mean 48 ± 15); 129 were men and 98 women. One hundred seventy-nine patients had the obstructive form of HC; 54 had the nonobstructive form. Eighteen patients had undergone ventricular septal myectomy, and 11 of them still had the obstructive form of the disease. Verapamil therapy was begun in these patients either because of persistent symptoms or because of a return to an unacceptable quality of life after operation.

Twenty-two patients were in chronic atrial fibrillation at the onset of verapamil therapy. Coronary arteriography was performed in 81 of the 227 patients before the therapeutic trial. Fifty-eight patients had no significant coronary artery disease (>50% diameter luminal narrowing), whereas 9 patients had significant 1-vessel disease, 8 had double-vessel disease and 5 had triple-vessel disease.

At the time of initiation of verapamil therapy, 190 patients had been taking β-blocking drugs, whereas in

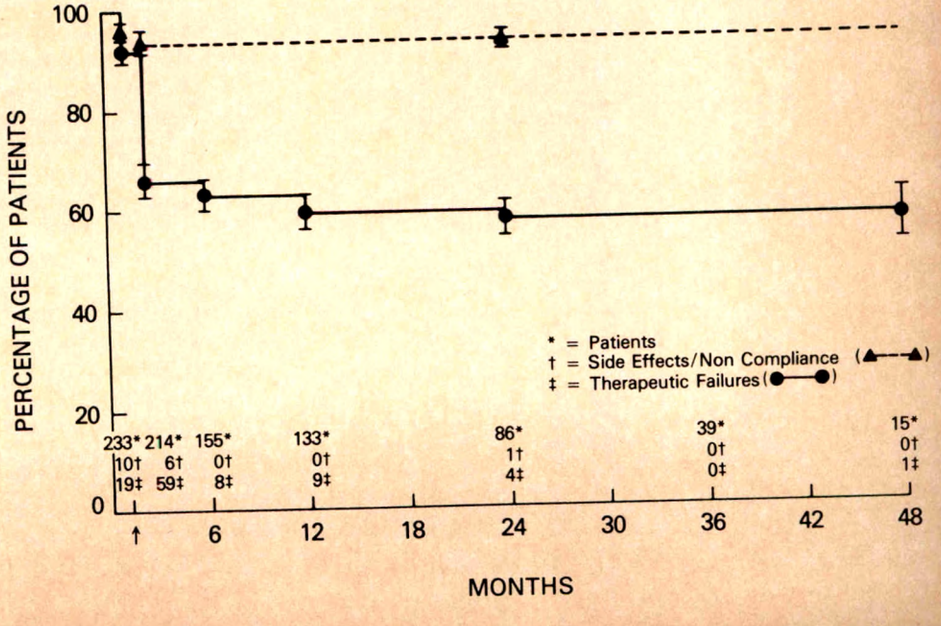

FIGURE 3. Plot of percentage of patients still taking verapamil after initiation of oral administration. Curves were obtained using method of Kaplan and Meier.[24] Upper curve (**broken line**) depicts those patients discontinuing verapamil because of adverse effects (16 patients) or noncompliance with protocol (1 patient). The lower curve shows all patients who discontinued drug independent of reason. Difference between curves is those patients in whom medication was stopped because of inadequate relief of symptoms (71 patients), death (9 patients) or loss to follow up (3 patients).

Nitrates	2
Antihypertensive drugs	1

39 patients β blockers had been discontinued because of either lack of efficacy or adverse reactions. β-blocking drugs were discontinued when verapamil administration was initiated. Only 4 patients (1 with severe obstructive lung disease and 2 with diabetes) had never received β blockers. Despite receiving what was considered to be optimal medical therapy, 11 patients were classified as New York Heart Association functional class IV, 158 as functional class III, 58 as functional class II and 2 patients as functional class I (in 1 patient the indication for therapy was repetitive supraventricular tachycardia; in the other repetitive sustained ventricular tachycardia). Functional class could not be adequately defined in 4 patients; in each of these verapamil therapy had been begun before referral to the National Institutes of Health.

The maintenance verapamil dose in patients who tolerated this medication was 120 to 640 mg/day (median dose 360). One hundred thirty-three patients (59%) were still taking verapamil 3 to 53 months (mean 25 ± 13) after initiation of therapy. Three patients were lost to follow-up study—2 after taking verapamil 18 months without complaints, 1 with whom we could not make contact during the 10 months since discharge. Verapamil dose in the 133 patients still being actively followed has been 80 to 720 mg/day (median dose 360).

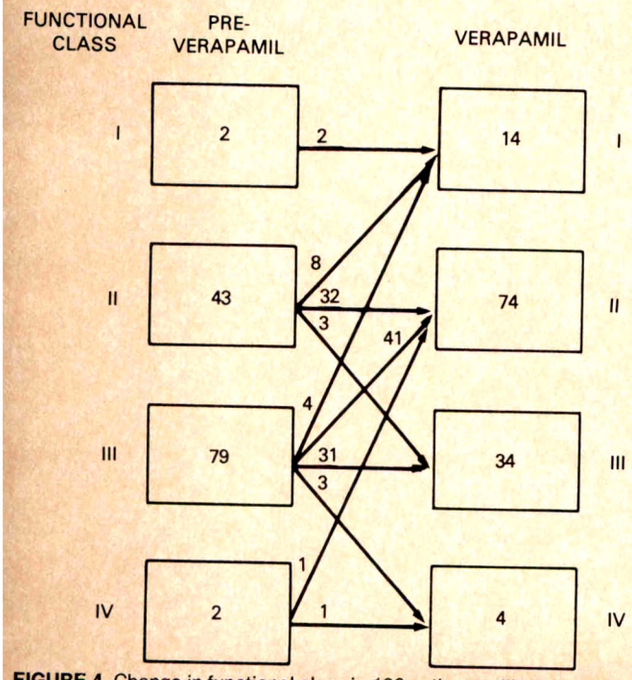

FIGURE 4. Change in functional class in 126 patients still taking verapamil. The patient group includes 2 patients lost to follow up, but whose functional class was known at time of last visit, 18 months after starting verapamil. Seven patients still taking verapamil are not included because their functional class could not be adequately defined either at time of initiation of verapamil therapy or at last follow up.

Among the 233 trials of verapamil therapy, the drug was stopped in 16 instances (7%) because of adverse drug effects and once because of a patient's inability to comply with the protocol. In 71 instances (30%), the drug was stopped because an acceptable quality of life was not obtained. Nine additional patients (4%) died while taking the drug. Three patients have been lost to follow up, and are counted as therapeutic failures. Figure 3 shows that all but 1 case of adverse effects and noncompliance occurred in the first 6 months after the initiation of therapy (59% occurred in the first month). Although 76% of the deaths and symptomatic failures occurred in the first 6 months of follow up, there is a consistent failure rate of 2.7% every 6 months thereafter. The patients with known coexisting coronary artery disease followed a course similar to the group as a whole, but long-term success was slightly reduced. Nine patients have remained with long-term verapamil therapy, 10 have undergone operation, 2 are taking other medication, and 1 has died.

The effect of verapamil therapy on functional class is shown in Figure 4. All 126 patients depicted have chosen to remain with verapamil therapy because of subjective symptomatic improvement or avoidance of adverse effects. We considered 5 of these to be therapeutic failures and surgery was recommended, but the patients chose to continue taking verapamil. Some of the patients required the addition or maintenance of other cardiac medication to achieve an acceptable lifestyle; these medications are listed in Table V.

Exercise testing: In 126 patients (including 11 with known coronary artery disease), a graded treadmill exercise test was performed with patients on no medication. Verapamil therapy was begun and the test was repeated in the hospital after the drug had been administered at least 5 days. This same procedure was performed 12 months later with 35 patients (1 with known coronary artery disease) and 24 months later with 32 patients (5 with known coronary artery disease). Table VI demonstrates that there was an initial improvement in exercise duration that was maintained at the time of follow up. Assessing the results of individual patients, and taking a 30% change in exercise duration as a definite change in exercise capacity, we found that 21% of patients had a further improvement over the long-term, 51% had a persistent improvement, and 28% had less of an improvement at their last outpatient test when compared with in-hospital values.

In 24 patients who had been taking verapamil for 1 year, exercise duration was determined after all medication had been stopped for 48 to 72 hours.[25] Although exercise duration without medication 1 year after the start of verapamil therapy was greater than before therapy was begun (8.3 ± 1.1 versus 6.7 ± 0.8 minutes), the difference did not achieve statistical significance. Figure 5 shows that 12 patients had an improved base-

‡ $p < 0.02$.

line exercise performance after taking the drug for 1 year, 8 had no change, and 4 had a decrease in baseline capacity.

Echocardiographic studies: In 32 patients who were maintained with verapamil because they achieved an acceptable quality of life, M-mode echocardiographic studies were performed according to techniques described previously[25] before starting verapamil and at an average follow-up time of 39 ± 8 months (range 24 to 53). Two of these patients had known coronary artery disease. Figure 6 demonstrates the results. Ventricular septal thickness was 22.2 ± 3.6 mm before verapamil administration and was reduced to 20.7 ± 4.0 mm ($p < 0.005$) at the time of last follow-up study. LV posterior wall thickness was 12.0 ± 2.0 mm before verapamil administration and 12.8 ± 2.5 (p = NS) at last follow up.

Nine patients had a change in ventricular septal thickness of ≥4 mm; in 8 it decreased, in 1 it increased. Two-dimensional echocardiograms were available for both studies in all 9 patients and were analyzed to try to determine whether the change in thickness measured on M-mode echocardiography was real or whether it could be ascribed to small alterations in transducer angulation that detected adjacent areas of left ventricle with different degrees of hypertrophy. This could produce an apparent, but not real, change in thickness if localized areas of thickening or thinning existed such that a slight change in the direction of the M-mode beam could move the beam from a relatively thick to a relatively thin area or vice versa. Apparent changes might also be detected if an echocardiogram was not of optimal quality, insofar as septal edges might not be properly identified. The analysis of the 2-dimensional studies indicated that the decrease in thickness appeared real in 2 patients, could be real or due to LV hypertrophy distribution in 2, were probably due to distribution of hypertrophy in 2 and were probably due to distribution or quality in 2. No patient had evidence of a myocardial infarction. In the 1 patient with an increase in thickness, it appeared to be due to LV hypertrophy distribution. Thus, the change appears to be real in 4 of 8 patients who had a decrease in septal thickness ≥4 mm, or in 13% (4 of 32) of the patients studied after verapamil treatment for a mean of 39 months.

Conclusions: The results of these investigations indicate that verapamil improves exercise capacity and

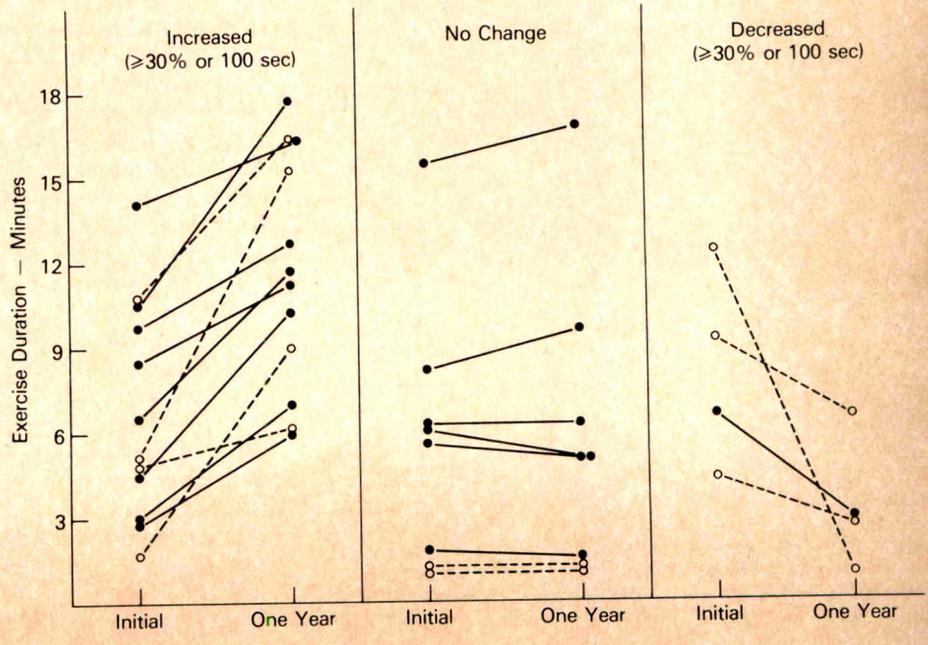

FIGURE 5. Exercise capacity of patients taking no cardiac medication before starting therapy with verapamil (initial) and 1 year later without cardiac medication after verapamil had been discontinued for 48 hours (1 year). **Left,** 12 patients had an increase in exercise capacity that could not be ascribed to variability inherent in testing technique and thus was considered significant. **Center,** 8 patients had no change; **right,** 4 patients had a significant decrease in exercise capacity greater than would be expected by random variation. **Open circles** and **broken lines** depict standard protocol exercise test and **closed circles** and **solid lines** depict augmented protocol exercise test. subjective symptoms during short- and long-term therapy in a group of patients with HC who previously had had an inadequate symptomatic response to conventional therapy with β-receptor blocking agents. These findings are similar to other long-term studies with verapamil.[20,26–28] In our patients, control hemodynamic findings, control exercise studies with patients not taking medication and initial improvement in exercise time shortly after verapamil was begun were not helpful in discriminating between those patients who were going to derive significant long-term clinical benefits from drug administration and those who were not.

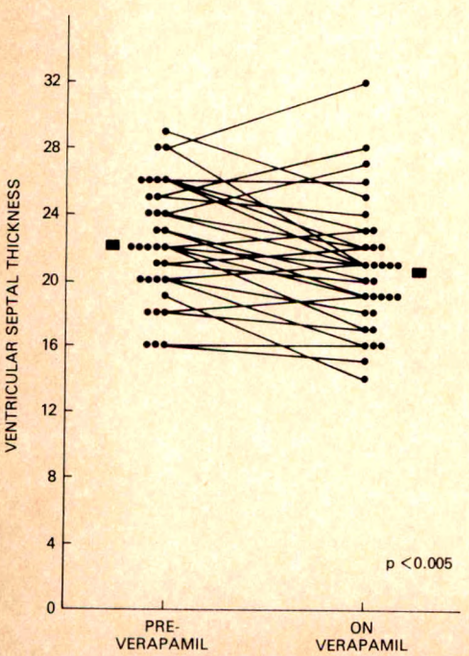

FIGURE 6. Echocardiographic measurements of ventricular septal thickness at time of last follow up in 32 patients who had been taking verapamil therapy for at least 24 months. **Horizontal bars** depict mean values.

Although verapamil produced no consistent changes in the patients' underlying functional capacity (exercise without any medication), 12 of 24 patients had an improved baseline exercise capacity that could not be ascribed to variability in the testing technique.[25] This improvement could have been caused by a training effect caused by a general increase in physical activity secondary to a more effective control of symptoms. Alternatively, it is intriguing to postulate that these 12 patients had an improvement in the underlying intrinsic cardiomyopathic process. Although ventricular septal and LV free wall dimensions were unchanged at 1 year,[25] a decrease in septal wall thickness was noted in a larger group followed for a longer period of time. Other investigators have reported similar findings in patients taking verapamil.[27–29]

Nonetheless, at this time it would be unjustified to conclude that verapamil alters the course of the basic disease process. Not only could the improved baseline exercise capacity be due to a training effect, but the biological significance of the 1.5 mm decrease in septal thickness is unknown. This latter finding must also be considered in the context of the fact that 2-dimensional echocardiographic studies have demonstrated the heterogeneous distribution of hypertrophy in these patients,[30] thus raising the question of whether M-mode echocardiography is a reliable technique for measuring changes in wall thickness in this disorder. Although the results of 2-dimensional echocardiography studies suggest that some patients have a real decrease in septal thickness while taking verapamil, no echocardiographic measurements in a control group of patients with HC

exist to compare with the apparent changes produced by verapamil.

Finally, even if such changes represent a significant verapamil-induced decrease in hypertrophy, they could be explained by a decrease in LV outflow obstruction and LV systolic wall stress reducing the stimulus for LV hypertrophy. Further work with 2-dimensional echocardiography or other imaging techniques and the use of control groups will be necessary to determine the significance of these exercise and echocardiographic findings.

No information is available at present regarding the effects of long-term nifedipine or diltiazem treatment of patients with HC.

Adverse Effects

Intravenous administration: Five of the 62 patients who received intravenous verapamil suffered an adverse electrophysiologic effect from the drug. Four patients had atrioventricular dissociation with a narrow QRS escape rhythm and 1 patient had Wenckebach block after PR prolongation to 0.40 seconds. All but 1 patient remained in a stable hemodynamic state and had the return of sinus rhythm within the few hours after discontinuation of the drug infusion. The 1 exception required ventricular pacing and phenylephrine infusion for several hours after leaving the catheterization laboratory.

Long-term oral administration: As described previously, most of the significant, potentially life-threatening adverse effects occurred early in the course of treatment. Table VII demonstrates that the most common were electrophysiologic and consisted of 24 patients who had atrioventricular dissociation (junctional escape rhythm in 23 and a ventricular escape in 1), 5 who had sinus arrest and 6 who had Wenckebach heart block. These effects disappeared with a decrease in dosage, and the majority of these patients continued taking verapamil; in 2, placement of a pacemaker was required. Seventeen patients had pulmonary congestion with verapamil whereas 12 others had significant, usually postural, hypotension. Thirteen of the 17 patients with pulmonary congestion had ≥50 mm Hg basal or provokable LV outflow tract gradients. The drug was stopped because of the development of pulmonary congestion in 4 of these patients; 3 others died while taking verapamil. The other 10 patients continued taking the drug, but had diuretics added to their treatment. Those with hypotension usually tolerated a decrease in dose. In 12 of these 59 patients who had serious adverse cardiovascular effects from verapamil administration, it was necessary to discontinue the drug; 3 others died while taking the drug. This represents 7% of the patients begun with verapamil therapy and includes 4 patients with adverse electrophysiologic effects, the 4 with pulmonary congestion and 2 with postural hypotension.

Included in this list of significant adverse drug effects are 4 patients who suffered adverse effects due to the administration of the combination of verapamil and quinidine. This figure represents 15% of the 27 patients taking both drugs. Three of these patients had severe

TABLE VIII Patient Deaths With Verapamil Therapy

Patient Initials	Age (yr) & Sex	History	PAW	LVOT Gradient	Time on Verapamil	Verapamil Dose/Day (mg)	Other Medications	Cause of Death
HLG	55M	CAD-CABG	10	Obst → Non (Oper)	18 months	640	Metoprolol, isosorbide dinitrate	Sudden, probable coronary death*
MMB	47F	. . .	. . .	Obst	26 months	360	Quinidine	Cancer of colon (better on verapamil)

postural hypotension with pulmonary edema developing in 2. The fourth patient had recurrent presyncope and syncope. Although this latter occurrence could have been the result of quinidine syncope or underlying disease, we have included it as an adverse reaction secondary to combination verapamil-quinidine therapy causing postural hypotension because presyncope and syncope decreased in frequency with the discontinuation of quinidine, and had not occurred when quinidine was administered alone before verapamil treatment. The mechanism presumed responsible for the adverse effect of combined quinidine-verapamil administration is a potentiation of verapamil's hypotensive action by the α-blocking effect of quinidine.[31] Two of the patients returned to long-term verapamil therapy alone without adverse effects.

Although we have included the occurrence of pulmonary congestion and postural hypotension as adverse effects of verapamil (or of verapamil and quinidine) therapy, it is possible that these adverse effects occurred *despite* verapamil therapy. This may be especially true in the 12 patients who had these occurrences after having taken verapamil for $\geq$1 month, compared with the 15 who had pulmonary congestion or hypotension soon after starting verapamil.

Less serious adverse effects occurred more frequently than the aforementioned adverse effects, but required cessation of treatment in only 4 patients, 1 each with upper gastrointestinal complaints, hair loss, vision disturbances and facial edema. Other types of adverse nuisance effects and their frequency are listed in Table VII.

Deaths: Nine patients died while taking verapamil therapy (Table VIII). Although the deaths in patients MMB, HLG, FBK, RO and FFR probably occurred *despite* verapamil therapy, the situation in the other 4 patients is not as certain. We have previously discussed how verapamil could initiate a series of electrophysiologic or hemodynamic events or both resulting in hypotension and, in patients with LV outflow tract obstruction, increased LV obstruction.[32] If the hypotension or increased obstruction or both is prolonged, decreased myocardial perfusion and pulmonary edema or cardiac arrest could result. Whether such events caused or contributed to the deaths of MLE, WAG, FRK and DRM is uncertain, but remains a reasonable possibility.

There are no available investigations examining the long-term effects of other calcium-channel blockers in this disease, so the incidence and types of adverse reactions are unknown. In our limited experience with nifedipine, we have seen the occurrence of pulmonary congestion and hypotension. Electrophysiologic problems with nifedipine should not occur, but given the known electrophysiologic effects of diltiazem,[33] adverse actions on the sinus and atrioventricular nodes similar to those described with verapamil can be anticipated.

In summary, verapamil offers an important alternative to β-blocker therapy in patients with HC. Nifedipine does not appear to have as beneficial hemodynamic or clinical effects in these patients, but has been found to be helpful in some patients with this disease; thus, it is reasonable to try nifedipine therapy in patients who have failed or do not tolerate verapamil. There are insufficient data on the efficacy of diltiazem, of combined calcium-channel and β-blocker therapy, or of combined calcium-channel–blocker therapy in these patients to draw any conclusions as to their value.

Because verapamil may cause serious complications in patients with HC, we have adopted the following policy regarding its administration to these patients. If alternative therapy is available, the drug is probably contraindicated in patients who have (1) increased pulmonary capillary wedge pressure (>20 mm Hg) in the presence or absence of obstruction of LV outflow, (2) a history of paroxysmal nocturnal dyspnea or orthopnea in the presence or absence of obstruction to LV outflow, (3) sick sinus syndrome without an implanted pacemaker, (4) significant atrioventricular junctional disease without an implanted pacemaker and (5) low systolic blood pressure, particularly in the presence of LV outflow obstruction. The drug should be given with caution to patients with systolic hypertension and marked obstruction to LV outflow, and moderate prolongation of the PR interval (>0.26 seconds) on the electrocardiogram. The same policy is followed regarding nifedipine administration, except for the caveats concerning electrophysiologic complications.

Because clinical findings do not always correlate with the measurement of mean pulmonary wedge pressure, we perform a right heart catheterization in all patients who are candidates for calcium-channel blocker therapy, and who have not had a recent catheterization (within 6 months) or who have had a worsening of symptoms since their last catheterization. If a mean wedge pressure >20 mm Hg is present, we usually will use other forms of treatment. It is not customary to administer the calcium-channel blocker in the laboratory for we have not found the short-term effects to be helpful in predicting the long-term effects of drug administration. In those patients who have significant increases in their mean pulmonary artery wedge pressure or evidence of atrioventricular or sinus node disease, we often do administer the calcium-channel–blocker in the catheterization laboratory to be sure the drug will not exacerbate these abnormalities. We only begin in-hospital drug therapy in those patients who are identified as being at relatively higher risk for having an adverse effect from their treatment.

Therapeutic Application of Calcium-Channel Antagonists for Pulmonary Hypertension

MILTON PACKER, MD

Calcium-channel antagonists may provide an effective approach to the treatment of pulmonary hypertensive disorders. Biochemical evidence suggests that pulmonary vasoconstriction results from the transmembrane flux of calcium into vascular smooth muscle; accordingly, the pulmonary pressor responses in experimental hypoxic pulmonary hypertension can be attenuated by verapamil and nifedipine. In patients with chronic obstructive lung disease, nifedipine decreases pulmonary artery pressures and pulmonary vascular resistance in proportion to the severity of hypoxemia before treatment. However, little pulmonary vasodilator effect is seen when hypoxemia is corrected by inhalation of oxygen, and systemic arterial oxygen desaturation can occur after nifedipine in patients breathing room air; most importantly, long-term studies in patients with chronic lung disease are lacking. In selected patients with primary pulmonary hypertension and other obliterative diseases of the pulmonary vasculature, nifedipine produces short- and long-term hemodynamic improvement at rest and during exercise, and these benefits are frequently paralleled by amelioration of dyspnea and fatigue. However, in patients in whom right ventricular function has been severely compromised by chronic pressure overload, both verapamil and nifedipine may exert notable depressant effects on right ventricular performance, despite the decrease in right ventricular afterload that would be expected to accompany a decrease in pulmonary vascular resistance. These negative inotropic actions may result in serious deleterious clinical reactions.

Although calcium-channel antagonists represent a promising approach to the management of patients with pulmonary hypertension, the long-term efficacy and safety of these drugs in this disorder remain to be established. (Am J Cardiol 1985;55:196B–201B)

Cor pulmonale consequent to long-standing pulmonary hypertension is a major cause of cardiovascular morbidity and mortality.[1] The obstruction to pulmonary blood flow in this disorder is principally the consequence of obliterative changes in the pulmonary vasculature, resulting from either a primary process within the pulmonary arteries or secondary to pulmonary parenchymal disease.[2,3] However, there is considerable evidence that the severity of the pulmonary hypertensive state may be exacerbated to varying degrees by reversible pulmonary arteriolar constriction.[4] This appears to be particularly true in patients with hypoxic pulmonary hypertension, in whom pulmonary vascular resistance may decrease dramatically after oxygen inhalation and who may benefit clinically from long-term oxygen therapy.[5]

Based on such encouraging results, several investigators suggested that attempts to dilate the pulmonary vasculature directly by the administration of vasodilator drugs might be therapeutically useful in the treatment of patients with pulmonary hypertension regardless of the underlying cause. Isolated reports of benefit have appeared with the use of α-adrenergic antagonists,[6,7] β-adrenergic agonists[8] and direct-acting vasodilator drugs[9–11] in both primary and secondary pulmonary hypertensive states. In many of these patients, the pulmonary vasculature seemed to be exquisitely responsive to pharmacologic interventions, and some of these persons had substantial hemodynamic and clinical improvement from long-term vasodilator therapy. Unfortunately, attempts to expand this therapeutic approach to a large number of patients have produced disappointing results; in subsequent trials, patients frequently failed to benefit, and serious adverse reactions were common.[12–14] Hence, the search continues for vasodilator agents that might prove to be more ef-

From the Division of Cardiology, Department of Medicine, Mount Sinai School of Medicine of The City University of New York, New York. fective and better tolerated than presently available drugs.

Because vasoconstriction is ultimately mediated by the intracellular interaction of calcium with myofibrillar elements within the vascular smooth muscle cell,[15] the use of drugs that block the transmembrane influx of calcium may provide a specific and effective approach to the treatment of pulmonary hypertension. This report reviews the evidence for and against the use of calcium-channel antagonists in primary and secondary pulmonary hypertensive disorders.

Theoretical Basis for Use of Calcium Antagonists in Treatment of Pulmonary Hypertension

Biochemical evidence: The potential usefulness of calcium antagonists in the treatment of patients with pulmonary hypertension is based on a number of independent lines of evidence that suggest that calcium plays a key role in the pathogenesis of pulmonary vasoconstriction. Biochemical studies in animals with chronic hypoxic pulmonary hypertension indicate that hypoxia causes a shift of calcium from extra- to intracellular sites.[16] With a decrease in ambient oxygen, the vascular smooth muscle cell accumulates calcium and contracts; this occurs because anaerobic glycolysis produces sufficient energy substrates to support contraction but not to maintain a transmembrane ionic gradient.[17,18] Consequently, the cell membrane depolarizes, leading to the influx of extracellular calcium, and, as the cytoplasmic levels of calcium increase, smooth muscle contraction occurs.[19] Hence, hypoxia causes pulmonary vasoconstriction by directly acting to depolarize the vascular smooth muscle cell and initiate transmembrane entry of calcium.[20–22] Accordingly, the administration of a calcium-channel antagonist may lead to pulmonary vascular relaxation by blocking the entry of *extra*cellular calcium.[19] The effects of calcium-channel blockage are in contrast to those of other pulmonary vasodilators, which appear to act exclusively on the *intra*cellular calcium pool, either by enhancing intracellular sequestration or by increasing extrusion of activator calcium.[19,23]

Experimental models of hypoxic pulmonary hypertension: Experimental models of pulmonary hypertension support the biochemical evidence suggesting that calcium plays an important role in mediating pulmonary vasoconstriction. In isolated, artificially perfused and ventilated rat lungs, McMurtry et al[24] showed that alveolar hypoxia produced an immediate and marked pulmonary hypertensive response, which was blocked by verapamil; a similar inhibitory effect was seen with nifedipine in isolated pig lungs by Kennedy and Summer.[25] In both studies, attenuation of pulmonary vasoconstriction occurred in a dose-dependent fashion, such that nearly complete abolition of the pulmonary pressor response to hypoxia was observed with high doses of both calcium-channel antagonists.

These findings were subsequently extended by several investigators to the intact animal. Tucker et al[23] showed that verapamil attenuated the pulmonary hypertensive effects of hypoxia in anesthetized dogs, and similar findings were observed with nifedipine in the same species by Young,[26] Bishop[27] and their co-workers. Young et al[26] studied the effects of equimolar concentrations of nifedipine, verapamil and diltiazem on hypoxic pulmonary hypertension in the anesthetized dog. They noted that nifedipine decreased pulmonary vascular resistance without a change in pulmonary artery pressures, and this beneficial effect was seen only during conditions of hypoxia; nifedipine exerted no pulmonary vasodilating effect when alveolar oxygen content was restored to normal. In contrast, verapamil and diltiazem exerted no vasodilating effects on the pulmonary circuit in this study regardless of the inhaled oxygen concentration. The lack of efficacy of verapamil and diltiazem was likely the result of the low doses used (all drugs were administered in equimolar rather than equipotent concentrations). When higher doses of verapamil were used in subsequent studies, its pulmonary vasodilating effects were found to be comparable to those of nifedipine.[28] All of these observations indicate that calcium-channel antagonist can exert selective dilating effects on the pulmonary vasculature and that these actions are preferentially exerted in states characterized by high vasoconstrictor tone.

The ability of calcium-channel antagonists to inhibit the pulmonary hypertensive response to stimuli other than hypoxia remains controversial. McMurtry et al[24] noted that verapamil exerted minimal effects on the pressor response to angiotensin II or prostaglandin $PGF_{2\alpha}$ in the isolated rat lung; they also observed a similar specificity for hypoxic stimuli in the anesthetized dog.[23] To explain these findings, the investigators suggested that prostaglandins mediated their pulmonary vasoconstrictor effects by acting on intracellular calcium stores, and, thus, their pressor responses were unaffected by drugs that acted at the cell membrane.[19,23] However, it is unclear whether such a simple conceptual model is valid, particularly in view of recent evidence that verapamil and nifedipine can inhibit prostaglandin-mediated pulmonary vasoconstriction.[26,28] There appear to be a number of mechanisms that may account for the attenuation of pulmonary vasoconstriction by calcium-channel blockade regardless of the site of action of the inciting stimulus. As stated earlier, verapamil and nifedipine may be effective because a stimulus acts directly to depolarize the smooth muscle cell and initiate transmembrane calcium influx.[20–22] Alternatively, calcium-channel antagonism may abolish the constrictor response by inhibiting the release of a humoral intermediate from secretory cells in the perivascular tissues,[29,30] because extracellular calcium plays a key role in excitation-secretion coupling.[31] Lastly, even if a substance exerts its pulmonary vasoconstrictor effects entirely by way of an action on intracellular calcium stores, calcium-channel blockade may depress the rate at which intracellular stores of calcium are replenished from extracellular sources, and, therefore, may interfere indirectly with the observed vasoconstrictor response.[32]

In contrast to the dramatic responses of verapamil and nifedipine in hypoxic pulmonary vasoconstriction of short duration (<1 hour), the effectiveness of calcium-channel blockade in experimentally induced

chronic hypoxic pulmonary hypertensive states is less clear. Verapamil's ability to attenuate the vasoconstrictor response to acute hypoxia may become progressively less marked with repeated hypoxic exposures.[23] This may explain why in unanesthetized calves confined in a hypoxic environment for 2 weeks, administration of verapamil produced only modest decreases in pulmonary artery pressure and pulmonary vascular resistance, and these pulmonary vasodilator effects were less marked than those seen with oxygen or after administration of a β-agonist agent.[33] These findings suggest that in pulmonary hypertensive states of long duration, biochemical changes may occur that limit the magnitude of vasodilation that can be achieved by calcium-channel blockade. If calcium is located primarily intracellularly in chronic hypoxic pulmonary hypertension,[16] the administration of drugs that act at the cell membrane may have little effect on the vasoconstricted state compared with agents that affect intracellular calcium transport (for example, β-adrenergic agonists).[19,33] In studies of long-term treatment with verapamil administered prophylactically to rats confined in a hypoxic atmosphere for 3 to 4 weeks, drug-treated subjects had less marked increases in pulmonary artery pressure and less pronounced hypertrophy of the right ventricle than did control rats, but the magnitude of observed benefit was small.[34,35] With more prolonged periods of hypoxia (comparable to those seen clinically), structural obliterative changes may take place within the pulmonary vessel walls from prolonged vasoconstriction[36]; these may result in irreversible obliterative changes in the pulmonary vasculature, which then become unresponsive to any pharmacologic intervention.[37,38]

Clinical Application of Calcium Antagonists in Patients with Pulmonary Hypertension

Hypoxic pulmonary vasoconstriction in chronic obstructive lung disease: Because calcium-channel blocking drugs proved efficacious in acute experimental hypoxic pulmonary vasoconstriction, verapamil, nifedipine and diltiazem were subsequently administered to patients with hypoxic pulmonary hypertension in an effort to achieve similar favorable hemodynamic results.[39–41] Simonneau et al[40] administered 20 mg of nifedipine sublingually to 13 patients with chronic obstructive pulmonary disease who had severe hypoxemia secondary to acute respiratory failure. While these patients were breathing room air, nifedipine produced a marked decrease in mean pulmonary artery pressure and pulmonary vascular resistance associated with a mild increase in cardiac output. The magnitude of the decrease in pulmonary vascular resistance correlated inversely with the control arterial oxygen tension; little pulmonary vasodilation was observed in patients whose control oxygen pressure was greater than 60 mm Hg. When oxygen tension was increased by breathing oxygen, pulmonary arterial pressure and pulmonary vascular resistance decreased to the same extent as with nifedipine, and there was no additional effect when nifedipine was added to oxygen therapy.

Preliminary work by Kennedy et al[42] indicates that nifedipine produces beneficial effects in hypoxic pulmonary hypertension in patients with chronic obstructive pulmonary disease who are clinically stable and not in acute respiratory failure. In a double-blind, placebo-controlled, crossover study, nifedipine decreased pulmonary vascular resistance at rest and attenuated the increase in pulmonary vascular resistance during exercise in 5 patients while they were breathing room air, but exerted little additional benefit when added to oxygen therapy. Similar hemodynamic responses to nifedipine were seen in patients with chronic obstructive lung disease studied by El Allaf,[43] Muramoto[44] and their co-workers.

Although encouraging, these results need to be interpreted cautiously. Investigators have long feared that the administration of pulmonary arterial dilating drugs to patients with secondary hypoxic pulmonary hypertension might lead to systemic hypoxemia.[6,7,14,45] This fear was based on the theory that the pulmonary vessels most likely to be pharmacologically responsive to vasodilator stimuli were those in which local hypoxia-mediated vasoconstriction prevented perfusion of hypoventilated alveoli; dilatation of these vessels could lead to significant venous admixture and decrease in systemic oxygen saturation.[45] It is of interest, therefore, that, in the studies of Simonneau,[40] Kennedy[42] and their co-workers, arterial oxygen tension decreased significantly with nifedipine, and was not reversed by oxygen administration. This is consistent with the concept that arterial desaturation is the result of transpulmonary shunting of blood through poorly ventilated alveoli. However, in both studies, oxygen transport to the peripheral tissues increased after nifedipine, because nifedipine therapy was accompanied by a significant increase in cardiac output. This is in contrast to the effects of nitrates in patients with chronic obstructive lung disease, which fail to increase cardiac output, and thus produce significant decreases in arterial tension and oxygen transport in patients with hypoxic pulmonary hypertension.[45]

Unfortunately, none of these early studies evaluated the long-term effects of calcium-channel blockade in patients with hypoxic pulmonary vasoconstriction. Although sustained amelioration of pulmonary hypertension can be obtained by 24-hour continuous-flow oxygen therapy,[5] it is not clear that similar long-term benefits will accompany the administration of nifedipine or other calcium-channel antagonists, even though the short-term effects of these agents are similar to those seen with oxygen.[40] Whereas oxygen therapy may produce long-term effects that exceed in magnitude the short-term responses,[33] the benefits of vasodilator therapy frequently diminish with time.[46] Resolution of these dilemmas awaits results for long-term hemodynamic studies and randomized clinical trials.

Primary pulmonary hypertension: Reports of the favorable effects of calcium-channel blockade in patients with hypoxic pulmonary hypertension have led to the application of these drugs to the treatment of patients with pulmonary hypertension of unknown

cause (primary pulmonary hypertension). Although the pathophysiologic factors that underlie the development of pulmonary hypertension in these patients remain unknown, the obliterative vascular lesions that characterize this disorder have long been thought to arise secondarily to abnormal pulmonary vasoconstriction.[37,47] Consequently, a number of vasodilator drugs have been administered to these patients in an attempt to attenuate the vasoconstrictive components of the disease and to forestall the development of irreversible vascular sequelae.[48] Although a variety of vasodilator drugs have been advocated for use in this disorder,[4,8,9,11,49] none has proved to produce consistent hemodynamic and clinical benefits.[12–14] The most serious disadvantage of this therapeutic approach is that most vasodilator drugs produce systemic vasodilation that is greater in magnitude than the degree of pulmonary vasodilation.[14] Under such circumstances, systemic vasodilation might occur without an increase in cardiac output and lead to severe hypotension;[14] on the other hand, if the cardiac output increases markedly in the absence of a comparable pulmonary vasodilator effect, pulmonary hypertension can be exacerbated.[48]

In contrast to traditional vasodilator therapy, however, calcium-channel antagonists appear to exert selective dilator effects on the pulmonary circulation and are preferentially active in vasoconstrictive states.[15,50,51] Hence, they might be particularly beneficial in the management of patients with primary pulmonary hypertension and other obliterative pulmonary vascular diseases. Theoretically, of the available agents, verapamil has particular appeal, because this drug exerts less marked effect on the systemic circulation than does nifedipine,[52] and thus may produce less hypotension than do drugs with pronounced systemic vasodilator actions.

A number of investigators have reported favorable effects of calcium-channel blockade in patients with primary pulmonary hypertension.[53–58] In a series of case reports, calcium-channel antagonism increased cardiac output and decreased pulmonary artery pressure and pulmonary vascular resistance at rest and during exercise; these hemodynamic effects were sustained for 2 to 6 months and were associated with an amelioration of symptoms of dyspnea and signs of right-side heart failure. Camerini et al[53] first reported the beneficial effects of nifedipine in a patient with primary pulmonary hypertension; nifedipine (100 mg daily) produced marked increases in cardiac output and decreases in mean pulmonary artery pressure and pulmonary vascular resistance, which were sustained for 3 months and were associated with marked symptomatic improvement. Similar short- and long-term hemodynamic and clinical effects were observed by De Feyter et al[54] in a patient who received treatment with nifedipine, 120 mg daily for 6 months. Saito et al[56] claimed to have observed beneficial effects with nifedipine, 30 mg daily for 1 year, in a patient in whom cardiac catheterization during therapy showed marked resolution of pulmonary hypertension compared with a previous catheterization performed 2 years earlier; however, the short-term effects of nifedipine were not assessed. Wise et al[55] reported on a patient with primary pulmonary hypertension in whom nifedipine, 40 mg daily, produced a marked increase in cardiac output and decrease in pulmonary artery pressure at rest and during exercise; treatment with nifedipine for 4 months produced substantial clinical benefits associated with persistent favorable effects on cardiac output but less marked effects on pulmonary artery pressure. Beneficial short-term hemodynamic responses to verapamil and diltiazem have also been reported,[57,58] and long-term treatment in some of these cases was followed by clinical improvement. Unfortunately, all of these reports are isolated case studies; we do not know how representative these findings are because each concerned an individual patient. Furthermore, the relation between any observed benefit and treatment with a calcium-channel antagonist is unclear, because in none of these cases was treatment withdrawn in order to determine whether benefits were directly related to the drug. This is important, because spontaneous hemodynamic improvement in patients with primary pulmonary hypertension may not be uncommon.[59,60]

Further experience in larger series of patients has generally supported the benefits of calcium-channel blockade. Rubin et al[61] evaluated 9 patients with primary pulmonary hypertension who were treated with nifedipine, 10 to 20 mg sublingually initially, followed by oral therapy with 40 to 160 mg daily for 4 to 14 months in 6 patients. Short-term treatment with nifedipine produced marked increases in cardiac output and decreases in total pulmonary resistance with notable decreases in pulmonary artery pressure in many patients. These favorable responses were associated with a significant decrease in right ventricular end-systolic and end-diastolic volumes and an increase in right ventricular ejection fraction as determined by radionuclide angiography, the magnitude of which correlated with the decrease in total pulmonary resistance. Long-term therapy produced persistent hemodynamic benefits associated with improvement in symptoms. Similar responses were seen by Olivari et al[62] in 7 patients with primary pulmonary hypertension. In this study, nifedipine, 20 mg sublingually, increased cardiac output and decreased pulmonary artery pressure and pulmonary vascular resistance at rest; these benefits were also observed in 3 patients during exercise. Unfortunately, no long-term results were reported. Mc Leon et al[63] noted similar immediate effects in 4 patients given 20 mg of nifedipine sublingually. Hemodynamic improvement was sustained after 4 months in the 2 patients who were invasively reevaluated while receiving a daily dose of 40 mg daily; total work capacity increased markedly.

However, adverse effects during calcium-channel blockade have been reported with increasing frequency as experience with these drugs has increased. Rubin et al[61] reported that a patient who failed to have a pulmonary vasodilator response with nifedipine had a marked increase in pulmonary artery pressure as cardiac output and heart rate increased consequent to

systemic vasodilation. This was probably the result of reflex activation of the sympathetic nervous system and is similar to the occasional exacerbations of pulmonary hypertension seen after administration of isoproterenol to patients with primary pulmonary hypertension.[13,48] Similarly, although nifedipine produced significant pulmonary vasodilation in the patients reported by Summer et al,[64] severe adverse reactions (hypotension and gastrointestinal distress) were seen in each of the 5 patients they treated. Even more serious adverse effects were seen in 9 patients with primary pulmonary hypertension treated with verapamil by Landmark et al.[57] Verapamil infused directly into the pulmonary artery produced marked decreases in pulmonary artery pressure but little change in cardiac output or pulmonary vascular resistance. In 3 patients, however, a marked decrease in cardiac index was observed; this was associated with dyspnea and hypotension in 1. These unfavorable responses to verapamil were attributed to its negative inotropic effects[15]; that similar deleterious effects were not reported with nifedipine was attributed to its less marked cardiodepressant action.[52]

Preliminary results from our laboratory, however, indicate that marked depressant effects on right ventricular function may accompany the use of both nifedipine and verapamil in patients with primary pulmonary hypertension. In 7 such patients who we treated with oral and intravenous verapamil[65] and in 6 patients treated with oral nifedipine,[66] pulmonary vascular resistance was decreased significantly in a fashion similar to the reports of other investigators. However, cardiac index failed to increase with either drug, despite the decrease in impedance to right ventricular ejection that would normally be expected to improve cardiac performance. This unexpected response was a consequence of a marked deterioration in right ventricular performance during treatment with both calcium antagonists, as reflected by a substantial decrease in mean pulmonary artery pressure (and, hence transpulmonary driving pressure) and a marked increase in right ventricular filling pressure. These deleterious responses differed markedly from those seen with hydralazine, which increased cardiac output in these same patients without significant effects on mean pulmonary arterial pressure or mean right atrial pressure. These unfavorable effects of verapamil and nifedipine were accompanied by severe adverse clinical events, including the precipitation of severe hypotension and cardiogenic shock during short-term therapy in 2 patients and the exacerbation of right-side heart failure during long-term treatment in 3 patients.

The detrimental effects we observed with calcium-channel blockade in our patients with primary pulmonary hypertension are in marked contrast to the favorable effects on right ventricular function reported by Rubin et al[61] and the resolution of clinical right-side heart failure during long-term therapy reported by Camerini et al.[53] The reasons underlying such differences are unclear, but they may be related to the severity of right ventricular dysfunction in our patients, all of whom had a right ventricular ejection fraction <30% and most of whom had a mean right atrial pressure >10 mm Hg. Right ventricular filling pressure was not generally measured in previous reports on the use of nifedipine in pulmonary hypertension, and only 1 group of investigators measured the right ventricular ejection fraction before therapy.[61] If the severity of right ventricular dysfunction in our patients were greater than in previous reports, it might explain the detrimental responses we observed, because the cardiodepressant effects of calcium-channel blockade are largely determined by the severity of preexisting ventricular dysfunction.[67] In patients with severe left ventricular dysfunction, both verapamil and nifedipine can exacerbate left-side heart failure.[67,68] Our results indicate that in patients with preexisting severe right ventricular dysfunction, both drugs can aggravate right-side heart failure as well, regardless of whether the cause is primary[65,66] or secondary[63] pulmonary hypertension. These cardiodepressant effects are consistent with the ability of both drugs to block transmembrane calcium in cardiac muscle and thus depress myocardial contractility.[15,69]

In summary, although calcium-channel antagonism provides a logical approach to the treatment of a variety of pulmonary hypertensive states, the beneficial responses to these drugs, have largely been observed only during short-term administration to well-compensated, carefully selected patients treated under close supervision. The long-term effectiveness and safety of this therapeutic approach remains to be established, particularly in view of the deleterious effects on right ventricular function that may accompany treatment with these drugs in patients with severely advanced disease. Calcium-channel blockade might prove useful in the treatment of patients with early or mild pulmonary hypertension (or both), because the pulmonary vasculature in such patients may still be responsive to vasodilator stimuli and their right ventricular performance may be less likely to be adversely affected by the negative inotropic effects of these potent cardioactive drugs.

Calcium-Channel Blockers in Prophylaxis and Treatment of Asthma

CHRISTOPHER H. FANTA, MD

Calcium-channel blocking drugs do not induce bronchoconstriction in susceptible persons with cardiac disease and concomitant hyperreactive airways (such as asthma or chronic bronchitis). The ways in which calcium blockers might in fact play a beneficial role in preventing bronchoconstriction or inducing bronchodilation in asthma are explored. Nifedipine and verapamil have been shown to inhibit the bronchoconstriction provoked by exercise, histamine, methacholine and antigen. The potential mechanisms by which this protective effect is mediated—whether by direct action on tracheobronchial smooth muscle, inhibition of release of mediators from activated mast cells or both—are examined by reviewing in vitro studies of both cell systems. Calcium blockers also exhibit some bronchodilating activity in vitro. Early clinical trials of these drugs in ambulatory asthmatic patients have shown little, if any, therapeutic benefit, but results must be considered preliminary in view of the nature of the short-term, small-scale trials performed to date. Regardless of their therapeutic potential in obstructive lung diseases, the calcium-channel blockers offer a powerful probe into the role of calcium in the physiologic make-up of airways and, in particular, the pathophysiologic features of airway hyperreactivity.

(Am J Cardiol 1985;55:202B–209B)

In the past, the physician treating a patient with both angina and asthma was faced with a difficult dilemma. The most potent antianginal medications available, the β-adrenergic blockers, were contraindicated in the presence of asthma, and the β-adrenergic stimulants frequently used to treat asthma were likely to exacerbate the angina. Now, with the introduction of calcium-channel blockers, a new class of drugs is available to treat angina and other cardiac diseases that has the potential for application in the subpopulation of patients with concomitant airway obstruction.

To the cardiologist, then, the airway effects of the calcium-channel blockers are important because of the lack of bronchoconstriction induced by these drugs. Unlike β-blockers, calcium-channel blockers do not exacerbate airway obstruction in susceptible persons.[1–3] In 1967, Atterhög reported that intravenous verapamil administered for control of cardiac arrhythmia caused no worsening of lung function in 3 patients with concomitant asthma. Subsequently, Ringqvist[2] administered 10 mg of verapamil intravenously to 9 subjects with moderately severe chronic obstructive lung disease and found no increase in their mean lung resistance. More recently, among a group of 18 patients with angina and either chronic bronchitis or asthma, Jaiprakash et al[3] found no deterioration in lung mechanics (1-second forced expiratory volume [FEV_1], vital capacity or airway resistance) during a 2-week period of treatment with nifedipine, 10 mg orally, three times daily. According to these studies, this new class of cardioactive agents is safe for use in patients with concomitant obstructive lung disease, including asthma.

To the pulmonologist, on the other hand, the attraction of the calcium-channel blockers is their potential for beneficial airway effects; that is, for inhibiting bronchoconstriction and inducing bronchodilation in reactive airway diseases. It is tempting to conceive of asthma as analogous to Prinzmetal's angina:[4] both bronchospasm and coronary vasospasm are exaggerated contractile responses of smooth muscle tissue. The contractile machinery of airway smooth muscle, as of coronary artery smooth muscle, is calcium-dependent and is regulated, at least in part, by the transmembrane influx of calcium ions.[5,6] The spectacular efficacy of calcium-channel blockers in treating Prinzmetal's angina[7] encourages the pulmonologist to explore the effect of calcium-channel blockade in bronchospastic disorders.

TABLE I Calcium-Channel Blockers in Exercise-Induced Bronchoconstriction (Additional Studies)

Report	Drug (Dose and Route)	Subjects (n)	Postexercise Decrease in Expiratory Flow (%)*		Significance (p Value)
			Placebo	Drug	
Patel[16]	Verapamil (approximately 3 mg inhaled)	10	45 ± 4	17 ± 4	<0.01
Patel[17]	Nifedipine (20 mg sublingually)	15	32 ± 4	22 ± 4	<0.01
Barnes et al[18]	Nifedipine (20 mg sublingually)	8	57 ± 4	36 ± 5	<0.01
Corris et al[19]	Nifedipine (20 mg sublingually)	8	24 ± 4	6 ± 5	<0.001

* Mean ± standard error of the mean.

In fact, multiple pathways in the pathogenesis of asthma are influenced by intracellular calcium ion concentrations and might be susceptible to manipulation by inhibitors of calcium ion influx.[8–10] Not only constriction of tracheobronchial smooth muscle but also mast cell degranulation, mucous gland secretion and vagal neurotransmission are mechanisms for airflow obstruction that may be modulated by the calcium ion. Of these latter 3 pathways, the role of calcium in mediator release from mast cells has been the most extensively studied. Extracellular calcium must be available for antigen-induced release of histamine from sensitized mast cells to proceed.[11] After antigen-antibody interaction on the cell surface (or stimulation with ionophores), altered membrane permeability occurs, which allows calcium to enter the cell; mediator release follows in direct proportion to calcium influx.[12] The ability to prevent calcium from entering into these cells might uncouple the antigen-antibody stimulus from the secretory response. The calcium-channel blockers have been found to interfere with secretory processes in other tissues, such as pancreas[13] and pituitary gland.[14] Their inhibition of release of the mediators of immediate hypersensitivity from mast cells could provide an important therapeutic intervention in asthma.

Prophylaxis of Exercise-Induced Bronchoconstriction

To explore the potential role of calcium-channel blockers in the prevention of bronchoconstriction, Cerrina et al[15] administered 20 mg of nifedipine sublingually to 10 asthmatic patients before exercise. Each subject performed 10 minutes of steady-state exercise on a bicycle ergometer on 3 separate occasions: once on a control day without any premedication, and then again on 2 additional days 30 minutes after premedication with either placebo or nifedipine in a single-blind fashion. Airflow obstruction was assessed by measuring peak expiratory flow rate (PEFR) and flow after exhalation of 50 and 75% of the vital capacity ($\dot{V}max_{50}$ and $\dot{V}max_{25}$). All 3 parameters demonstrated a mean decrease of approximately 40% from baseline values after exercise on the control and the placebo premedication days, but no deviation from the normal range when exercise was preceded by nifedipine administration (Fig. 1). These investigators found that nifedipine completely protected asthmatic subjects from exercise-induced bronchoconstriction. At the same time, they found that sublingual nifedipine (20 mg) failed to alter resting lung function in another group of 10 asthmatic patients.[15]

Subsequent to this dramatic initial report, 4 studies have confirmed a beneficial effect of the calcium-channel blockers in exercise-induced bronchoconstriction, but the protection observed has been more modest.[16–19] The results of these studies are summarized in Table I. Bronchoconstriction was significantly inhibited by premedication with either sublingual nifedipine or inhaled verapamil; but, as the mean postexercise values for expiratory flow indicate, protection was only partial. In each study the investigators reported considerable intersubject variability: a few subjects had complete inhibition of bronchoconstriction, a few had no inhibition and most had partial inhibition by a calcium-channel blocker.

Cromolyn is widely used clinically as prophylactic therapy in exercise-induced asthma.[20] Patel[17] compared the effect of inhaled verapamil (approximately 3 mg) with inhaled cromolyn (approximately 12 mg by nebulized solution) in exercise-induced bronchoconstriction and found virtually identical protection.

Prophylaxis of Inhalational Challenges: Histamine, Methacholine and Antigen

Because the role of mediator release in the pathogenesis of exercise-induced bronchoconstriction remains controversial,[21,22] the finding that calcium blockers have a protective effect in this setting does not help to localize their site of action. As illustrated schematically in Figure 2, calcium-channel blockers may exert their inhibition by blocking mast cell degranulation, by directly interfering with bronchial smooth muscle contraction or by both mechanisms. One approach to this question is to assess the effect of these agents on bronchoconstriction triggered by stimuli other than exercise, where the pathways for constriction are better defined. Examples of such stimuli include histamine, which is thought to induce bronchoconstriction through both reflex (vagal) pathways and direct stimulation of smooth muscle receptors; methacholine, which acts like a cholinergic neurotransmitter to stimulate smooth muscle constriction directly; and antigens, which of course trigger mast cell secretion. In recent years, a number of reports have emerged examining the effect of calcium-channel blockers in these various circumstances, both in man and in animal models. The results of these studies, which are reviewed herein, are not entirely consistent. On the whole, however, they do provide evidence for a direct action of the calcium-channel blockers on tracheobronchial smooth muscle.

Histamine and methacholine inhalational tests in asthmatic patients: Four studies of asthmatic patients have found that sublingual nifedipine decreases the bronchoconstrictive response to inhaled histamine.[18,19,23,24] In 3 reports (from 2 different laboratories)[18,19,23] the concentration of histamine provoking a 20% decrease in FEV_1 (PC_{20}) was calculated by administering incremental concentrations of inhaled histamine in dose-response fashion. The mean PC_{20} for histamine after premedication with nifedipine was approximately 2 to 3-fold greater compared with placebo pretreatment. In the fourth study,[24] the mean fall in FEV_1 after a fixed concentration of inhaled histamine was 32 ± 15% (standard error of the mean) after placebo versus 22 ± 12% after nifedipine ($p < 0.01$). In 1 study reporting no protective action of sublingual nifedipine,[25] there was a wide range of bronchial reactivity among subjects; mean values showed a nonsignificant trend toward a higher PC_{20} for histamine after nifedipine, and in 4 of 8 subjects the PC_{20} was 2 or more times greater after nifedipine compared with placebo.

Similarly, nifedipine has been shown to blunt the bronchospastic response to inhaled methacholine, both in asthmatic patients[24] and in patients with coronary artery disease but without airway hyperreactivity.[26] These reports suggest an action of the calcium-channel blocking drugs independent of any mast cell effects, probably an action at the level of airway smooth muscle itself.

The protective benefit afforded in these bronchoprovocative challenges is, however, quite modest. Direct comparisons with frequently used bronchodilating drugs are few. In 1 investigation of 15 asthmatic patients,[27] repetitive histamine dose-response inhalation tests were performed on a single day with premedication randomized to saline solution, verapamil and salbutamol; all 3 were administered by nebulizer. Approximately 2.5 mg of verapamil and 1.0 mg of salbutamol were nebulized; more precise estimates of inhaled or retained doses were not made. Verapamil increased the PC_{20} for histamine 1.8-fold (not a significant increment when compared with saline solution), whereas salbutamol caused a 16.8-fold increase. Others have also found that inhaled sympathomimetics, in delivered doses as low as 200 μg, increase the PC_{20} for histamine or methacholine 10-fold or more.[28,29] One must be cautious, however, in extrapolating these laboratory data using bronchoprovocative agonists to clinical therapeutics. For example, the *oral* administration of bronchodilating drugs such as salbutamol or a theophylline preparation before histamine or methacholine challenge alters responsiveness by a factor of only 2 to 3.[28,29] Based on this limited protection, one would not predict their widespread clinical utility.

In vitro studies of tracheobronchial smooth muscle: In vitro experiments using human bronchial spirals[30,31] and tracheal strips[32] have lent support to the

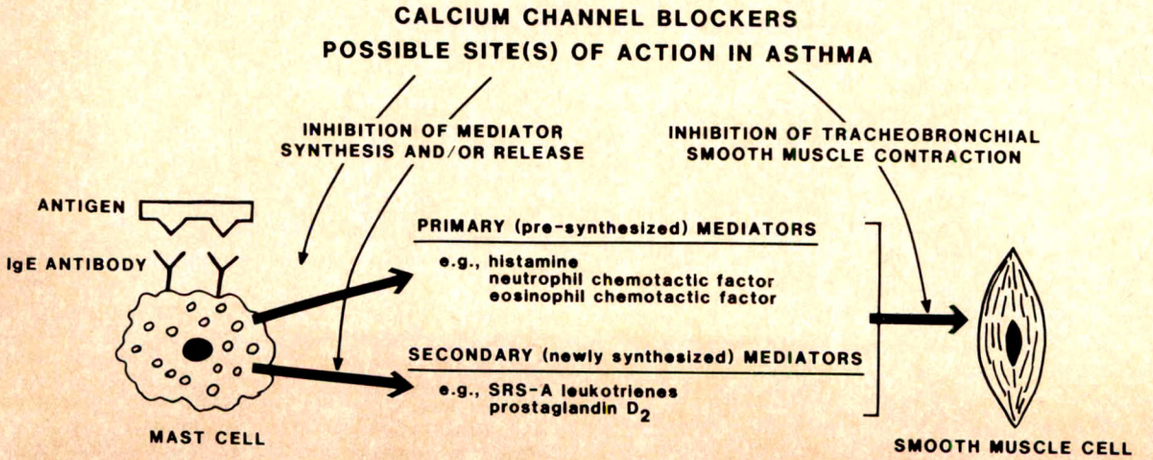

FIGURE 2. Schematic representation of mast cell, mediators of immediate hypersensitivity and target tracheobronchial smooth muscle cell, indicating possible sites of action of calcium-channel blockers.

theory that calcium-channel blockers directly inhibit contraction of tracheobronchial smooth muscle, which is the final common pathway for acute bronchospasm. Drazen et al[32] prepared strips of trachealis muscle from autopsy material, generally obtained within 8 hours after death. These strips were suspended in glass organ baths, bathed with a physiologic solution and gassed with 95% oxygen and 5% carbon dioxide. One end of each strip was fixed to a transducer for recording of contractile force. This tracheal tissue was shown to constrict in dose-response fashion to incremental concentrations of histamine added to the organ bath. Two reproducible concentration-effect curves could be generated in succession. When nifedipine (3 μM) was incubated with the tissue strips for 10 minutes before a second concentration-effect sequence was performed, contraction of the trachealis muscle was significantly inhibited (Fig. 3). At the highest histamine concentration (100 μM), nifedipine inhibited constriction by 50 ± 2%. Verapamil has likewise been shown to inhibit histamine-induced constriction of human bronchial strips.[31]

This inhibitory effect is not limited to a specific antagonism of histamine. Studies with human bronchial smooth muscle have demonstrated inhibition of acetylcholine-induced constriction as well,[30] and animal studies using guinea pig and canine airway tissue strips have extended the spectrum of bronchoconstrictor agonists inhibited by calcium blockers to include potassium, carbachol, serotonin, prostaglandin $F_{2\alpha}$ and leukotriene D_4.[5,33–37] Thus, specific antihistaminic or anticholinergic properties of calcium blockers cannot account for their observed effects. That calcium blockers' mechanism of action is based on their influencing calcium availability for the cytostolic contractile apparatus is supported by the observation that their inhibitory effect on tracheobronchial smooth muscle contraction can be overcome by increasing the extracellular calcium concentration.[35] This has also been demonstrated for coronary vascular smooth muscle.[38]

Inhibitory activity of calcium blockers is not limited to central airway tissue, as represented by tracheal spirals. The same inhibition of constriction has been demonstated using lung parenchymal strips,[35] which contain contractile elements from peripheral airways.

The duration of protection against pharmacologically induced bronchoconstriction afforded by the calcium-channel blockers has been examined in a canine model.[39] After a single intravenous injection of 200 μg/kg of nifedipine in anesthetized beagles, protection was observed within 15 minutes, reached a maximum at 60 to 90 minutes and persisted against repetitive histamine challenges for up to 240 minutes.[39] In these dogs, a delivered dose of aerosolized nifedipine of only 140 μg also protected against histamine-induced increases in pulmonary resistance, but the duration of action by this route was briefer (60 minutes).[39]

Sources of calcium for tracheobronchial smooth muscle contraction: From the studies cited previously, it would seem reasonable to conclude that calcium flow into tracheobronchial smooth muscle can be stimulated by a variety of bronchoconstrictor agonists; that by blocking this calcium ion influx the calcium-channel blockers can inhibit bronchoconstriction; and that inhibition of histamine- and methacholine-induced constriction in man can be achieved by this mechanism of action after administration of standard drug doses. Yet some questions remain. Why don't calcium-channel blockers provide more complete protection against bronchoconstriction? Why does submaximal airway constriction still take place, even in the presence of relatively high concentrations of channel blockers in vitro? One possible explanation invokes differential tissue sensitivites to drug activity between airways and other clinically more responsive tissues, such as the coronary vasculature. However, when potassium-induced contractions of coronary artery and trachea are compared in vitro, nifedipine exhibits virtually identical concentration-dependent inhibitory activity in the 2 tissues, as shown in Figure 4,[40] (even though this comparison is between 2 different animal species).

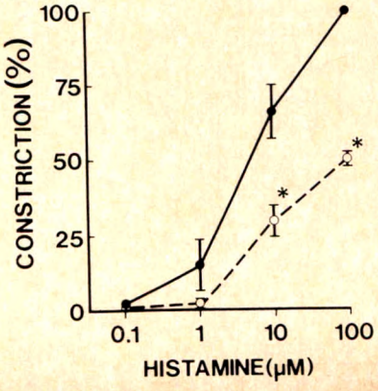

FIGURE 3. Inhibition of constriction of human tracheal strips in vitro. **Closed circles** and **solid lines** represent control tissues; **open circles** and **dashed lines** represent tissues preincubated with nifedipine, 3 μM. Each point is the mean of 6 tissues; parallel lines enclose 1 standard error of the mean. Reprinted with permission from Fanta.[77]

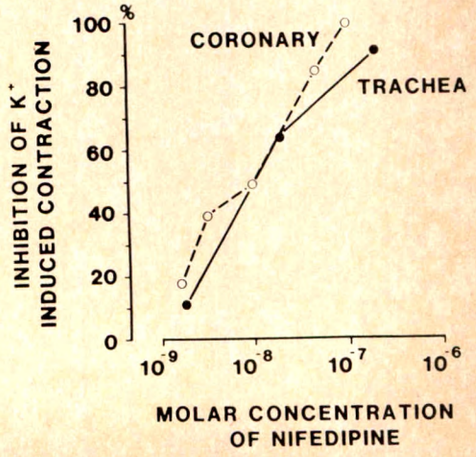

FIGURE 4. Comparison of inhibition of contraction of pig coronary artery strips and guinea pig tracheal strips in vitro. Coronary tissue was constricted with 43 mM extracellular potassium; nifedipine was then added to organ bath in increasing concentrations.[40] Tracheal strips were preincubated with varying concentrations of nifedipine before constriction with 60 mM potassium (unpublished observations).

Rather, the explanation may be that pharmacologically induced constriction of tracheobronchial smooth muscle makes calcium available to the contractile apparatus through routes other than those acted upon by calcium-channel blockers.[41] The following observations support this contention. Increased levels of extracellular potassium depolarize trachealis muscle; contractile tension develops in direct proportion to membrane depolarization ("electromechanical coupling"), and this contraction is virtually entirely dependent on calcium influx from the extracellular fluid.[42,44] In relatively low doses, the calcium-channel blockers completely abolish potassium-induced contraction of tracheal smooth muscle.[5,37,45,46] On the other hand, pharmacologic bronchoconstrictors such as histamine, acetylcholine and serotonin cause tracheal contraction that is in large part independent of membrane depolarization, especially at higher drug concentrations.[6,42,44] This "pharmacomechanical coupling" is less dependent on the influx of extracellular calcium than is potassium-induced contraction,[6,45] although the intracellular pools of calcium presumed to be activated by the constrictor drugs do become depleted over time if extracellular calcium is not made available to replenish them.[6,42,45,47] Calcium-channel entry blockers only partially inhibit mediator-induced constriction; they are less active by 100-fold or more as inhibitors of contraction caused by leukotriene D_4,[47] histamine[37,46] or acetylcholine[37,48] than they are against potassium-induced contraction. Thus, even in the presence of calcium-channel entry blockers, pharmacologic agents can initiate receptor-mediated events that make calcium available to the contractile apparatus. This mechanism probably involves intracellular sources of calcium as well as transmembrane calcium flux unimpeded by calcium blockers, similar to the "receptor-operated channels" described for vascular and other smooth muscle.[49] Thus, it is not surprising to find incomplete protection from histamine or methacholine-induced bronchospasm in asthmatic patients pretreated with presently available calcium-channel blocking drugs.

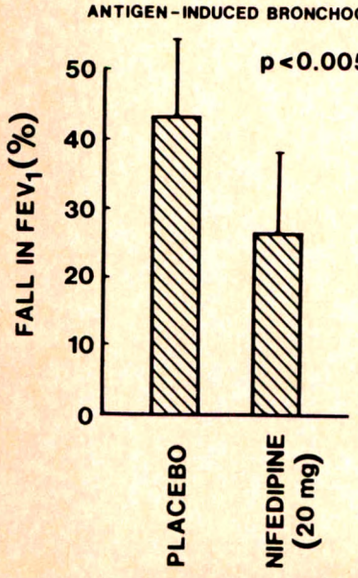

FIGURE 5. Inhibition of antigen-induced bronchoconstriction by nifedipine. Fall in FEV_1 equals decrease in 1-second forced expiratory volume from before to after antigen challenge. The mean and 1 standard error of the mean are shown for 8 subjects. (Adapted from Henderson et al.[30])

Antigen inhalation challenges in asthmatic patients: Inhalation of antigen in the allergic asthmatic patient triggers a complex series of events: over the short term, antigen binds to IgE antibodies on the surface of mast cells; "bridging" between adjacent IgE molecules triggers alterations in the cellular plasma membrane; calcium enters the cell and there follows the release of presynthesized mediators of immediate hypersensitivity, such as histamine, as well as the generation and release of newly synthesized mediators, such as slow-reacting substance of anaphylaxis (SRS-A).[50] Besides this acute or "early-phase" reaction inhaled allergens may also form circulating antigen-antibody complexes, leading to delayed or "late-phase" inflammatory reactions.[51]

Sublingual nifedipine has been shown to inhibit the acute bronchospastic response to inhaled allergen in asthmatic patients. Henderson et al[30] administered nifedipine, 20 mg, or placebo in double-blind fashion to 8 grass-pollen–sensitive asthmatic patients 30 minutes before challenge with inhaled grass-pollen antigen. A single dose of antigen was given on both drug and placebo days; the dose was selected on a previous day and was sufficient to cause at least a 25% decrease in FEV_1. Data from this study are shown in Figure 5. The mean decrease in FEV_1 in response to inhaled antigen was 43 ± 10% after placebo pretreatment and 27 ± 12% after nifedipine ($p < 0.005$). The degree of protection afforded by the calcium-channel blocker varied considerably from subject to subject: in 3 of the 8 subjects the percent decrease in FEV_1 with nifedipine was less than half that with placebo.[30]

Two other groups of investigators were unable to demonstrate altered responsiveness to antigen challenge by premedication with a calcium-channel blocker.[52,53] These discordant results may be explained in part by use of a different calcium blocker (verapamil) through a different route of administration (inhalation).[52,53] In 1 of these studies with negative results, sublingual nifedipine was also tested[52]: the provocative dose of allergen required to cause a 20% decrease in FEV_1 (PD_{20}) was the outcome variable measured. Because of the day-to-day variability in antigen-provocation testing, a 10-fold increase in PD_{20} was considered necessary to demonstrate a significant change from placebo. This degree of protection was not provided by the single dose of nifedipine.

Animal studies have confirmed that calcium-channel blockers can modify the airway response to inhaled antigen.[54,56] In Basenji greyhound dogs, a model of spontaneously occurring nonspecific airway hyperreactivity, aerosolized nifedipine (12.5 mg delivered dose) significantly reduced the increase in pulmonary resistance and the decrease in dynamic compliance caused by inhalation of Ascaris suum antigen.[54] The 40% ethanol solution in which nifedipine was dissolved

had no effect on lung function in control studies. Nifedipine aerosol also blunted the bronchoconstrictive response to inhaled methacholine and citric acid in these dogs.[54] On the other hand, although completely blocking antigen-induced bronchoconstriction in Ascaris-sensitive sheep, intravenous verapamil (150 μg/kg) had no influence on histamine or carbachol inhalation challenges in these animals.[55] These latter findings at least raise the possibility that, in sheep, parenteral verapamil exerted its protective effect by preventing mast cell activation in the absence of significant direct bronchial smooth muscle effects.[55]

In vitro studies of mediator release: The effect of calcium-channel blockers on mast cell activity has been investigated in vitro. Using rat peritoneal mast cells, it has been possible to demonstrate that the transmembrane influx of calcium initiated by antigen-IgE antibody binding can indeed be inhibited by preincubating the mast cells with a calcium blocker (in this case, nifedipine).[57] However, the impact of this calcium-entry blockade on mediator release is not straightforward.

Nifedipine blunts ionophore-induced release of histamine from human basophils.[58] In contrast, when antigen-induced release of histamine was analyzed using leukocyte suspensions from patients with hay fever,[59] passively sensitized fragments of human lung tissue[31] or an anaphylactic model of guinea pig trachea,[37] high concentrations of nifedipine or verapamil failed to modify antigen-stimulated histamine release. On the other hand, when SRS-A is the mast cell product assayed, decreased amounts are found when lung fragments[31,60] or peripheral blood neutrophils[61] are stimulated after preincubation with a calcium-channel blocker. Unlike histamine, SRS-A, which is now known to be a mixture of the leukotrienes C_4, D_4 and E_4, is synthesized de novo from arachidonic acid at the time of antigen stimulation.[50] The enzyme phospholipase A_2, which liberates arachidonic acid from membrane phospholipids, and the 5-lipoxygenase enzyme system, which initiates the conversion of arachidonic acid to the leukotriene metabolic pathway, are both calcium-dependent.[63,64] Calcium depletion will thus inhibit SRS-A leukotriene formation as well as release.[65] It may be, then, that by reducing transmembrane calcium ion flux into mast cells, calcium-channel blockers may inhibit leukotriene synthesis while not affecting secretion of the prepackaged histamine-containing granules.[66] This suppression of leukotriene release, although permitting histamine release to proceed unattenuated, has been described in a number of other circumstances, such as challenge with antigen in the presence of cytochalasins or certain concentration ratios of sympatho- and parasympathomimetics.[50]

A combination of cromolyn and a calcium-channel blocker in the prophylaxis of antigen-induced bronchoconstriction has not been reported, nor has the effect of calcium blockers on the "late-phase" of airway obstruction after antigen challenge been investigated.

Bronchodilating Action of Calcium-Channel Blockers

On the basis of these laboratory data regarding the prophylaxis of induced bronchoconstriction, it would be difficult to predict the role of calcium-channel blockers in routine outpatient management of patients with symptomatic asthma. Uniformly, investigators have found no bronchodilating effect of single doses of nifedipine or verapamil when given to subjects with mild, asymptomatic asthma recruited for bronchoprovocation testing.[15–19,23–25,27,30,52,53] However, in vitro studies would suggest that calcium-channel blockers can indeed exert a bronchodilating action.

Only a small, usually insignificant relaxant effect has been observed when calcium blockers were incubated

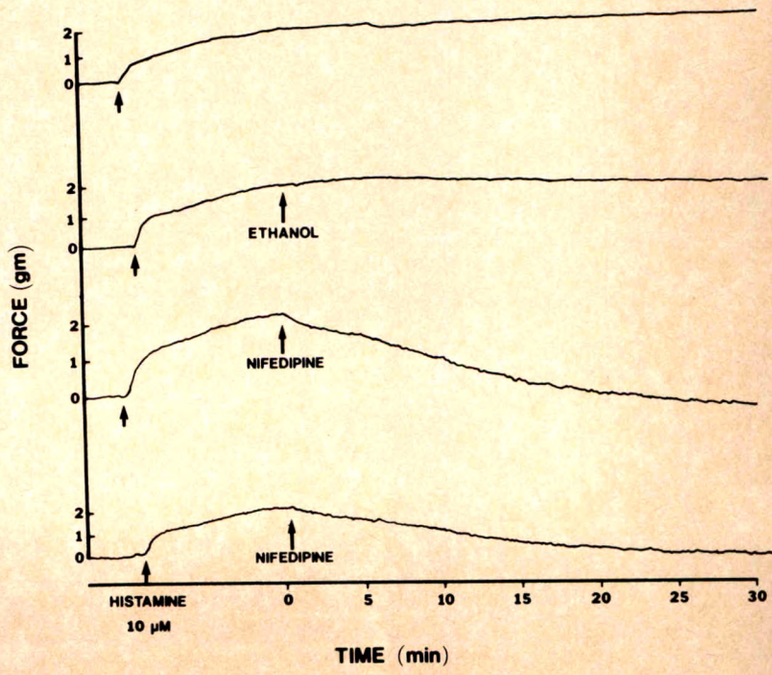

FIGURE 6. Nifedipine-induced relaxation of human tracheal strips in vitro. Actual strip chart recordings for 4 human tracheal strips are shown. Each was initially constricted by incubation with 10 μM of histamine. To **top strip,** nothing was added; to **second strip,** 0.1% ethanol (diluent for nifedipine); to **third** and **bottom strips,** nifedipine, 3 μM. Reprinted with permission from Drazen et al.[32]

with tracheal or lung parenchymal strips held at resting levels of tension.[30,32,35,47] This observation is somewhat surprising, given the finding that exposure to a calcium-free bath causes marked relaxation of resting tone in guinea pig trachea.[67] On the other hand, calcium-channel blockers will cause relaxation of guinea pig and human tracheal strips previously constricted by various pharmacologic agonists or by anaphylaxis[32,37,68–70] (Fig. 6). This bronchodilating action may vary depending on the agent used to promote bronchoconstriction: Weichman et al[47] found that nifedipine showed only a weak ability to relax leukotriene D_4-induced contraction of trachealis muscle while completely reversing contraction elicited by potassium. Differences in bronchodilating potency among the calcium-channel blockers probably also exist, with nifedipine having greater activity than verapamil or diltiazem.[47,71]

Using guinea pig tracheal tissue as an in vitro assay, the bronchodilating activity of calcium-channel blockers was compared with other bronchodilating agents. The concentration of diltiazem causing 50% relaxation of a maximum histamine-induced contraction (approximately 10^{-4} M diltiazem) is of the same order as that of theophylline[37,72] but is 1,000 or more times greater than for isoproterenol.[68,72] In an in situ preparation of canine trachea, intraarterial injection of nifedipine, 10 μg, produced less tracheal dilation than 0.1 μg of isoproterenol.[71] The mechanisms by which isoproterenol and calcium blockers achieve airway smooth muscle relaxation differ: the former is inhibited by propranolol, the latter appear not to be.[68] There exists the potential, therefore, of synergistic effects when the 2 classes of drugs are used in combination. In vitro evidence for such potentiation of bronchodilation by calcium-channel blockers has been contradictory to date.[33,68] However, enhancement of the bronchodilating effect of isoproterenol[68] and theophylline[73] by calcium blockers has been reported for guinea pig airway tissue in vitro.

Treatment Trials in Asthma

Adequate clinical trials of the calcium-channel blockers in patients with symptomatic asthma are lacking. One double-blind, placebo-controlled, crossover trial of oral verapamil was conducted in 10 asthmatic patients in 1970.[74] No change in FEV_1 or vital capacity, measured weekly, was observed during verapamil treatment as compared with placebo. However, the dosage of drug used, 40 mg 3 times daily, is now recognized to be far below the range at which maximal therapeutic effects are likely to be seen.[40] More recently, a group of 11 asthmatic patients was given nifedipine, 10 mg orally 3 times daily, or placebo for 4 days each in a randomized, double-blind, crossover protocol.[75] In these patients, all of whom had significant bronchoconstriction at rest (mean FEV_1 51%), a single oral dose of nifedipine, 10 mg, caused significant bronchodilation; the mean increase in FEV_1 2 hours after ingestion was 18% (versus 4% after placebo; $p < 0.05$). Eight of the 11 patients used an inhaled sympathomimetic throughout the protocol period. Patients self-recorded their PEFRs using Wright peak flowmeters at home. No differences were found between nifedipine and placebo treatment periods with respect to morning or evening PEFR determinations. The investigators reported that the nocturnal decrease in PEFR, a feature of the disease in all 11 patients, was decreased by a statistically significant amount during nifedipine treatment. However, because symptom scores recorded each morning by the subjects did not differ from 1 treatment period to the other, the clinical importance of this observation is dubious. Without question, additional clinical studies are needed to evaluate more fully the bronchodilator potential of the calcium-channel blockers, both alone and in combination with traditional bronchodilators. The available evidence does not indicate that the calcium-channel blockers currently in use are potent bronchodilators. However, as stated by Weiss et al,[37] the potential remains that eventually "control of calcium dynamics may offer innovative therapeutic modalities in the management of bronchial asthma."

Finally, it has been suggested[4,41,76] that disordered calcium metabolism may prove to be the basis for the underlying airway hyperreactivity that characterizes asthma. For the most part, this concept is pure speculation. The observation of Weiss and Viswanath[67] that after anaphylaxis, guinea pig trachealis muscle exhibits a heightened sensitivity to extracellular calcium may be pertinent. Calcium-channel blockers may help to elucidate abnormalities of calcium entry into cells or exaggerated contractile responses to intracellular calcium ion concentrations in patients with asthma.

In summary, calcium-channel blocking drugs are an important contribution to the therapy of patients with angina and concomitant reactive airway disease because they do not exacerbate airflow obstruction in such susceptible persons. Furthermore, they act to inhibit bronchoconstriction induced in asthmatic patients by a variety of stimuli, including exercise, histamine, methacholine and allergens, although in general their protection is limited. They appear to exert their effect by a direct inhibitory action on contraction of tracheobronchial smooth muscle. Inhibition of antigen-induced histamine release from human mast cells has not been demonstrated. However, calcium-channel blockers may interfere with the synthesis or release of leukotrienes from lung tissue, and some of their protective role in the prevention of bronchoconstriction may be through this mechanism of action. Adequate clinical trials of calcium-channel blockers in patients with asthma and other obstructive lung diseases are needed. Presently available evidence does not point to a major bronchodilator role for these drugs; they do serve, however, as a powerful probe into the role of calcium in airway physiology and in the pathophysiologic features of asthma.[77]

Calcium-Channel Blocking Agents for Gastrointestinal Disorders

DONALD O. CASTELL, MD

Calcium-channel blocking agents have a potential role in regulation of gastrointestinal tract function by decreasing smooth muscle contraction and possibly inhibiting cellular secretion. Most studies to date have concentrated on the ability of these drugs to inhibit smooth muscle contraction. Verapamil and diltiazem have been shown in animals (opossum, baboon) to produce decreased contractions in esophageal smooth muscle, resulting in a decreased amplitude of peristalsis and decreased lower esophageal sphincter pressures. In studies in man, oral doses of diltiazem and nifedipine have likewise been shown to have similar effects on the esophagus. At present, there is no experimental evidence of a major antisecretory effect of these drugs. In clinical trials, nifedipine has been shown to have a greater effect than placebo in improving symptoms in patients with achalasia, and diltiazem has been suggested as potential therapy in patients with chest pain secondary to excessive esophageal contraction. The precise role for calcium-channel blocking drugs in therapy of gastrointestinal disease is still being explored.

(Am J Cardiol 1985;55:210B–213B)

The calcium-channel blocking drugs verapamil, nifedipine and diltiazem relax smooth muscles by inhibiting membrane fluxes of calcium into the cells. The active inhibitory effects demonstrated by these agents on vascular smooth muscle raise the question of the potential for similar effects on smooth muscle of the gastrointestinal tract.[1] In addition, the secretory functions in the gastrointestinal glands have all been shown to be dependent to some degree on intracellular calcium shifts. Thus, effects on gastric acid, pancreatic enzyme and bicarbonate secretion and even intestinal fluid output might conceivably be modified by drugs that inhibit calcium entry.

Pharmacologic Studies in Animals

Pharmacologic studies to date have primarily addressed the effects of calcium-entry blocking agents on contraction patterns in the smooth muscles of the gastrointestinal tract. Further, most studies have looked at the action of these drugs on the smooth muscle portion of the esophagus, primarily because of the greater ease of studying the contraction patterns of this area of the gastrointestinal tract (Table I). The opossum has been a popular animal model for studies of esophageal function because of its size and the similarity of its esophageal muscular structure to that of humans. Studies of verapamil (64 μg/kg/min) in opossum reveal a gradual decrease in lower esophageal sphincter (LES) pressure during verapamil infusion with a gradual recovery upon cessation of infusion. A decrease in arterial blood pressure was also noted in these animals.[2] In this study, verapamil was also shown to cause a significant decrease in the amplitude of esophageal contractions produced by direct vagal stimulation. It should be noted that the infusion dose used in this study (64 μg/kg/min) is considerably larger than maximal doses of this drug reported in human studies (21 μg/kg/min) and produced significant decreases in arterial blood pressure.

A subsequent study with verapamil was performed using intravenous infusions in chair-restrained, awake baboons.[3] Using dose-response studies, a dose of 80 μg/kg/min was shown to decrease LES pressures by 74%. In addition, both the amplitude and duration of the peristaltic contractions in the smooth muscle portion of the distal esophagus were significantly decreased (about 50%) during infusion. No effect was noted on the contraction patterns in the upper esophagus (striated muscle). Peristalsis was initiated by a small bolus of water placed in the posterior pharynx, thus more closely simulating a primary peristaltic response. As in the opossum studies, a significant decrease in arterial blood pressure was noted during the infusions. The maximum decrease in mean arterial pressure was approximately

TABLE I Summary of Published Reports of Effect of Calcium-Channel Blocking Agents on Esophageal Contractions

	Drug	LES Effect	Amplitude Effect
Pharrmacologic Studies in Animals			
Animal			
Opossum[2]	Verapamil	↓	↓
Baboon[3]	Verapamil	↓	↓
Baboon[4]	Diltiazem	↓	↓
Pharmacologic Studies in Humans			
Type Patient			
Normal[9]	Nifedipine	↓	↓
Diffuse Spasm[9]	Nifedipine	↓	↓
Normal[10]	Diltiazem	None	None
"Nutcracker esophagus"[10]	Diltiazem	None	↓
Normal[11]	Nifedipine	↓	↓
Clinical Trials			
Type Patient (n)			Symptom Response
Achalasia (20)[13]	Nifedipine		++
Achalasia (15)[14]	Nifedipine		±
"Nutcracker esophagus" (9)[10]	Diltiazem		++ (no placebo)

LES = lower esophageal sphincter.

40%. In an attempt to establish that the esophageal contraction pressure changes were not secondary to the hypotension, a similar degree of hypotension was produced by serial bleeding of these animals. With up to 40% decrease in arterial pressure, no significant changes in esophageal pressures were produced. It was concluded that verapamil produced a significant action independently at both the esophageal smooth muscle and the vascular smooth muscle sites. In a subsequent report, the investigators also reported similar effects on esophageal contraction pressures in the baboon with intravenous infusions of diltiazem.[4]

These initial animal studies indicated that calcium blockers would decrease esophageal contraction pressures if given in sufficient amounts. The associated decreases in arterial blood pressure raised questions concerning the true potential for their clinical use and indicated the need for further studies with tolerable doses in man.

There are no reports at present on the effects of any of the calcium-entry blocking agents on contraction pressures in the remainder of the gastrointestinal tract or on secretory effects in animals.

The suggestion that agents that block calcium-entry into muscle cells might inhibit contractions of esophageal body musculature and LES is not unprecedented. Previous in vitro studies have identified an important role for intracellular calcium in esophageal smooth muscle contractions. Cohen and Green[5] have shown that muscle strips from the region of the LES in the opossum demonstrate a decrease in both peak force of contraction and maximum velocity of shortening in response to decrease in calcium concentration in the perfusing medium.[5] Similar in vitro studies by Fox and Daniel[6] demonstrated both decreased tone and diminished "off" contractions in muscle strips from the sphincteric region of the opossum esophagus when exposed to calcium-free solution. Other in vitro studies by deCarle et al[7] showed that decrease in calcium content produced a decrease in LES muscle tone and also abolished contraction of longitudinal muscle and "off" response contractions of circular muscle from the esophageal body. These in vitro observations support the in vivo responses found in more recent studies of calcium-entry blockade by verapamil and diltiazem.

Pharmacologic Studies in Humans

Calcium dependence of the contraction of human esophageal peristalsis in vivo has been previously demonstrated in normal volunteers by Danielides and Mellow.[8] In this study, calcium infusions producing significant increases in serum calcium concentrations resulted in a significant increase in the amplitude and the change in pressure with time (dP/dt) of esophageal peristaltic contractions in the smooth muscle esophagus. No effect was noted on the duration or velocity of peristaltic waves.

The first pharmacologic testing of a calcium-entry blocking agent in man was reported in 1981. In studies with nifedipine involving normal volunteers and patients with esophageal motility disorders, significant effects were observed on esophageal contractions. After an oral dose of nifedipine, 20 mg, significant decreases in resting LES pressure and in amplitude of peristaltic contractions were noted in normal subjects.[9] In addition, patients with diffuse esophageal spasm had significant decreases in LES pressure and peristaltic contraction amplitudes. These patients were also shown to have significant decreases in the amplitudes of their nonperistaltic "spastic" contractions and a decreased frequency of spontaneous "spastic" contractions. Although slight decreases in mean arterial blood pressure were noted, the patients did not have symptoms of hypotension.

In this same report, the investigators described their studies of the possible effect of nifedipine, 20 mg orally,

on gastric emptying. Dual-isotope labeling of both solid and liquid components of a meal was performed in normal subjects and patients who had prior gastric surgery. No effect of nifedipine on gastric emptying could be demonstrated.

In a recent study in our laboratory, we have measured the effect of diltiazem in a group of patients with recurring chest pain and high amplitude peristaltic contractions (the "nutcracker esophagus").[10] Significant decreases ($p < 0.05$) in both amplitude and duration of esophageal peristaltic contractions were found with single doses of 90 and 150 mg orally. These effects are illustrated in Figure 1. No significant decrease in systemic blood pressure was noted at these dose levels.

More recently, Hongo et al[11] have reported studies on the effects of nifedipine on esophageal contractions in normal subjects. Decreases in amplitude of esophageal peristalsis were reported with doses of 30 and 40 mg. No significant decrease in blood pressure was reported. These studies are summarized in Table I.

Recent preliminary studies in 10 patients with irritable bowel syndrome have shown that oral nifedipine, 20 or 40 mg, decreased colon motility.[12] Intraluminal rectosigmoid pressures measured during graded balloon distention were significantly decreased. Further studies were suggested to evaluate the therapeutic role of nifedipine in patients with irritable bowel.

To date there have been no reported studies on the effects of verapamil on gastrointestinal smooth muscle in man. Except for the aforementioned studies, there have been no reported human pharmacologic studies on the effects of these drugs either on contraction pressures in other areas of the gastrointestinal tract or on secretory functions.

The pharmacologic studies in animals and humans provide evidence that calcium-entry blocking drugs offer potential as therapeutic agents in conditions associated with excessive contractions of gastrointestinal smooth muscle, particularly in the esophagus.

Clinical Trials

Brief clinical trials of patients with esophageal motility disorders have been performed with calcium-blocking agents (Table I). To date, most of these trials involved nifedipine, although some data are available with diltiazem. Because of its characteristic pathophysiologic defect of very high LES pressure and incomplete relaxation during swallowing, achalasia is an entity in which these drugs have potential therapeutic value. In 1 placebo-controlled trial, the effect of nifedipine (10 to 20 mg sublingually 30 minutes before meals) was evaluated in 20 patients with achalasia. When studied for a period of up to 18 months, "excellent or good results" were noted in most patients evaluated by clinical grading of symptoms including dysphagia, chest pain and weight loss. The clinical improvement with nifedipine was significantly greater than that noted with placebo. This study suggested that nifedipine might be used in the medical treatment of patients with mild-to-moderate achalasia.[13]

A subsequent study compared the effect of nifedipine with isosorbide dinitrate in the treatment of achalasia.[14] In a crossover study design, 15 patients were treated with both nifedipine (10 mg orally 30 minutes before meals) or isosorbide dinitrate (5 mg sublingually 10 minutes before meals). Subjective improvement in dysphagia was reported in 13 patients receiving nitrate and only 8 receiving nifedipine. Headache and other adverse effects were more prominent during nitrate therapy. This study was only mildly enthusiastic about the potential effectiveness of nifedipine in the treatment of achalasia, reporting a better effect with nitrate therapy. It is quite difficult to draw any major conclusion concerning medical therapy of achalasia from this study.

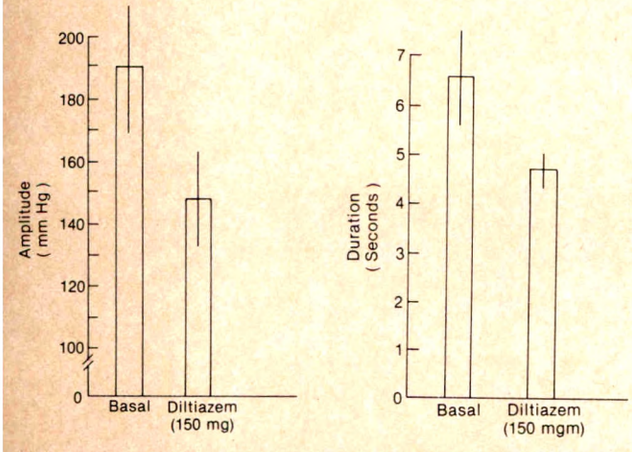

FIGURE 1. Left, mean amplitude of esophageal peristaltic contractions in 10 patients with high amplitude peristalsis ("nutcracker esophagus") before (Basal) and 120 minutes after a single oral dose of diltiazem (150 mg). Vertical lines indicate ± standard error of the mean. A significant decrease ($p < 0.05$) in mean amplitude occurred. **Right,** mean duration of esophageal peristaltic contractions in 10 patients with nutcracker esophagus both before (Basal) and 2 hours after an oral dose of diltiazem (150 mg). Vertical lines indicate ± standard error of the mean. A significant decrease ($p < 0.05$) in mean wave duration occurred.

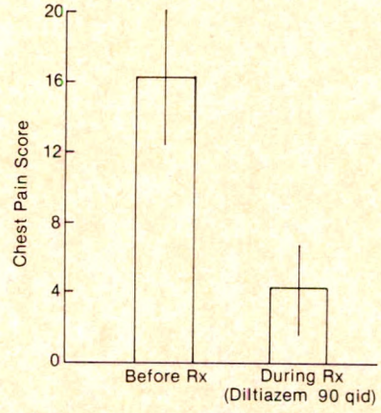

FIGURE 2. Mean chest pain score in 9 patients with nutcracker esophagus obtained before therapy and during an 8-week trial of diltiazem (90 mg 4 times daily). Score was obtained from the product of intensity and frequency of chest pain during each week of therapy. From a maximum potential value of 6 for each factor, a maximum potential score of 36 was possible. Mean values are shown from the group during week before therapy and during eighth week of treatment. The vertical lines indicate ± 1 standard error of the mean. A significant decrease ($p < 0.05$) in mean pain score occurred.

We have obtained preliminary observations on the use of diltiazem in the treatment of patients with the nutcracker esophagus.[10] Over an 8-week study period, significant improvement in incidence and severity of recurring chest pain was noted in 9 patients treated with diltiazem, 90 mg 4 times daily (Fig. 2). The results of this uncontrolled study were quite encouraging and a placebo-controlled trial is currently underway.

There is minimal information available in the potential therapeutic effects of calcium-channel blocking agents in other gastrointestinal disorders. Because of the profound effect of these agents on esophageal smooth muscle, it is reasonable to speculate that similar actions would occur in smooth muscle in other areas of the gastrointestinal tract, particularly in the colon. Likewise, because of the dependence of many secretory processes on intracellular calcium, one might readily propose that excessive secretory conditions might respond to drugs of this kind. These observations have led to speculations, and some empirical trials, of the efficacy of calcium-channel blocking agents in the therapy of a number of other gastrointestinal conditions, including irritable bowel syndrome, gastric hypersecretory states, acute pancreatitis and various diarrheal states. The role of calcium-blocking agents in the treatment of gastrointestinal disorders involving abnormal contraction patterns or abnormal secretion has received limited study at present. There are exciting potential uses for these drugs in a number of gastrointestinal disorders that remain to be explored.

Second-Generation Calcium Antagonists: Search for Greater Selectivity and Versatility

BRAMAH N. SINGH, MD, DPhil, SHERRIN BAKY, MS,
and KOONLAWEE NADEMANEE, MD

Calcium antagonists have a variable specificity for cardiac and peripheral activity. Based on such activity, these compounds, new and old, can be classified into 4 categories. Type 1 agents, typified by verapamil, its congeners (tiapamil and gallopamil) and diltiazem, prolong atrioventricular nodal conduction and refractoriness with little effect on ventricular or atrial refractoriness. These actions, to a large extent, account for the antiarrhythmic properties of this type of calcium antagonists. Type 2 agents include nifedipine and other dihydropyridines. In vivo, these agents are devoid of electrophysiologic effects in usual doses and concentrations. They are potent peripheral vasodilators with some selectivity of action for different vascular beds; their overall hemodynamic effects are dominated by this peripheral vasodilatation and reflex augmentation of sympathetic reflexes. Type 3 agents are flunarizine and cinnarizine (piperazine derivatives); in vitro and vivo, they are potent dilators of peripheral vessels, with no corresponding calcium-blocking actions in the heart. Type 4 agents (perhexiline, lidoflazine and bepridil) have a broader pharmacologic profile; they block calcium fluxes in the heart, in the peripheral vessels or in both. They may inhibit the fast channel in the heart and have other electrophysiologic actions. A clear understanding of the varied pharmacologic properties of the different classes of calcium antagonists is likely to provide a rational basis for the use of the newer agents in clinical therapeutics. Future development may produce agents with a greater tissue selectivity on the one hand and a broader pharmacologic profile and therapeutic spectrum of activity on the other.

(Am J Cardiol 1985;55:214B–221B)

Although more than 20 years have passed since the prototype of calcium antagonists was introduced, rapid advances in our understanding of the pharmacodynamic effects of these agents and their clinical applications followed only after Fleckenstein[1,2] provided important conceptual framework in the early 1970s. The pioneering work focused attention on the selectivity of effects of calcium antagonists on the myocardial slow channel, most readily demonstrable in isolated preparations using the voltage clamp technique.[3] The electrophysiologic effects of such agents as verapamil and prenylamine[2] in cardiac muscle were found to be similar to those produced by calcium-free media. The slow channel could be blocked to a substantial degree with concentrations of the drugs that had little or no effect on the fast sodium channel. Agents with this selectivity of myocardial action also had the propensity to block calcium fluxes in vascular smooth muscle; thus, they were all peripheral and coronary vasodilators. It soon became clear, however, that the so-called calcium-antagonist compounds (defined primarily as those agents that produced excitation-contraction uncoupling in cardiac muscle by blocking the slow channel) manifested a bewildering heterogeneity in chemical structure and were not completely selective for the myocardial slow channel. Some agents were truly selective for the slow channel in extremely low concentrations (for example, the dihydropyridines), and others blocked the slow as well as the fast channel in approximately the same drug concentrations (such as perhexiline). An appreciation of these differences led Fleckenstein[2,4] to divide calcium antagonists into 2 categories, but these may no longer be adequate to account for the diversity of effects of all calcium antagonists, new and old. For example, there appear to be differences in the potencies

of individual calcium antagonists with respect to their ability to block the slow channels in both cardiac and smooth muscle. Whereas a truly cardioselective agent (that is, one that blocks the slow channel in the heart and has no effect on vascular smooth muscle) has not been reported, the converse has been. For example, cinnarizine and flunarizine in vivo appear to competitively antagonize calcium fluxes in vascular smooth muscle; yet they have no effect on cardiac muscle in the same concentrations.[5] In addition, whereas lidoflazine also selectively inhibits the slow channel in vascular smooth muscle as opposed to the myocardial slow channel, it has the added propensity of blocking the fast channel in the heart.[6] Another dimension of complexity has been identified by radioligand binding studies,[7] which have demonstrated that different calcium antagonists display a diverse spectrum of antagonism toward selective tissues, a phenomenon that may have far-reaching therapeutic possibilities.

This report provides an expanded and clinically relevant classification of calcium antagonists as a framework for the discussion of the properties of some of the newer therapeutic agents that are promising and are likely to be introduced in the United States in the near future.

Classification of Calcium Antagonists

In 1977, Fleckenstein[4] suggested that calcium antagonists could be classified into 2 categories. He placed such agents as verapamil, diltiazem and nifedipine and its derivatives, which have a marked selectivity for inhibiting the slow channel versus the fast sodium channel in the heart, into 1 group. He placed such agents as prenylamine, terodiline, fendiline and perhexiline, which also inhibit the slow channel but have a broad array of other electrophysiologic actions, into another group. However, the expanding knowledge of the electropharmacologic features of these and newer agents suggests a need for an alternative classification. The one proposed in Table I was developed along clinical lines. It, too, may eventually need modification because the clinical and experimental data relating to calcium antagonists continue to increase rapidly.

As outlined in Table I, it appears useful to create 1 category for those calcium antagonists that impede conduction across the atrioventricular (AV) node and prolong its refractoriness in vivo. Such compounds include verapamil and its congeners (gallopamil and tiapamil) as well as diltiazem (Fig. 1). Electrophysiologically, these agents have qualitatively (but not necessarily quantitatively) similar effects and are thus likely to have a similar spectrum of antiarrhythmic properties. They are of particular value in the treatment of certain supraventricular tachyarrhythmias. These drugs also have the capacity to depress myocardial contractile function in vivo.

The second proposed class of calcium antagonists (Fig. 2) is represented by the numerous dihydropyridine derivatives (nifedipine, nitrendipine, nisoldipine, nimodipine, niludipine and nicardipine). These agents exert a depressant effect on sinus nodal frequency and inhibit AV conduction in vitro but not in vivo. Because all are potent peripheral vasodilators, the unopposed reflex increases in heart rate, AV conduction and contractility that they produce have a significant effect on the overall hemodynamic and electrophysiologic properties of these compounds. The dihydropyridine derivatives may be extremely effective as afterload-reducing agents in the control of certain hypertensive

TABLE I Clinical Classification of Calcium Antagonists

Type 1: Calcium antagonists with in vivo myocardial, electrophysiologic and vascular effects
Verapamil
Gallopamil (D-600)
Diltiazem
Tiapamil
Type 2: Calcium antagonists with predominant vascular effects in vivo
Nifedipine
Nitrendipine
Nisoldipine
Nimodipine
Nicardipine
Niludipine
Felodipine
Type 3: Calcium antagonists with selective vascular effects
Cinnarizine
Flunarizine
Type 4: Calcium antagonists with complex pharmacologic profile
Bepridil
Lidoflazine
Perhexilene

emergencies.[8] Conversely, because of the unopposed reflex effects, especially tachycardia and augmented contractility, they may aggravate myocardial ischemia in patients with fixed coronary lesions. These drugs also have the potential to depress myocardial contractile function in vivo but they are much less potent in this regard than the type 1 agents.

The third type of calcium antagonists (Fig. 3), characterized by the piperazine derivatives cinnarizine and flunarizine, may be regarded as having "reversed" specificity insofar as they appear to have few or no direct myocardial effects while having the propensity to block calcium movements in the peripheral vascular smooth muscle cells. It may even be argued whether these agents are calcium antagonists in the sense first conceived by Fleckenstein,[1] but pharmacologically it appears acceptable to view these compounds as having unique selectivity for vascular tissues.

Finally, there is a heterogeneous group of compounds (Fig. 4) that in certain concentrations block the myocardial slow channel and dilate the peripheral and coronary vessels, but also have other complex electrophysiologic actions. For example, perhexiline blocks both the fast and the slow channels in the heart at approximately the same concentrations. It uses one mechanism to increase the effective refractory period of tissue dependent on the slow channel for depolarization and another for tissue dependent on the fast channel. This agent is thus likely to have a wider spectrum of antiarrhythmic activity than those drugs that act solely from effects on the slow channel. In contrast, lidoflazine has no significant effect on the slow channel in the heart while it does have such an effect in vascular smooth muscle; it inhibits the fast channel and, like quinidine, has a modest effect in lengthening the action potential duration in ventricular muscle and Purkinje fibers. Perhaps the most complex pharmacologic actions are exerted by the drug bepridil. Bepridil appears to have the myocardial and peripheral effects of such type 1 compounds as verapamil. Yet it also inhibits the fast sodium channel while lengthening the action potential duration in most cardiac tissues. Thus, bepridil has the propensity to increase the voltage as well as the time-dependent refractoriness in the conducting and working fibers of the heart, while its effect on the slow channel in the slow-channel dependent tissues is similar to the electrophysiologic properties of verapamil. Calcium antagonism is therefore only one feature, albeit an important one, in the pharmacologic properties of this type of calcium antagonists.

A detailed appreciation of the net pharmacologic effects of these varied compounds will permit the rational basis for their clinical utility to be established. What follows is a discussion of the properties of some of the newer compounds, with the emphasis on recent developments particularly relevant to the expanding therapeutic roles of calcium antagonists in cardiovascular disease.

Type 1: Calcium Antagonists with In Vivo Myocardial Effects

The chemical structures of diltiazem, tiapamil and gallopamil (D-600) are shown in Figure 1 relative to that of the reference calcium antagonist, verapamil. Except for diltiazem, there are structural similarities among the other 3 compounds. All 4 are moderately potent peripheral vasodilators and are likely to have significant clinical utility in the control of mild-to-moderate essential hypertension. Their predominant electrophysiologic actions are lengthening conduction time and prolonging refractoriness in the AV node, properties that account for their known antiarrhythmic effects. The hemodynamic effects of verapamil in experimental

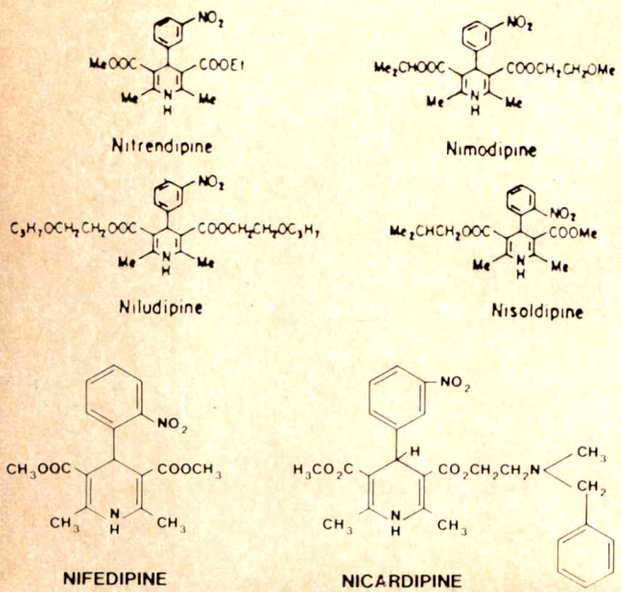

FIGURE 2. Chemical structure of some of the dihydrophridines, type 2 of calcium antagonists. Note that a minor difference in the structure may lead to variations in pharmacologic properties (see text). This category of calcium antagonist offers the greatest scope for studying structure-activity relations.

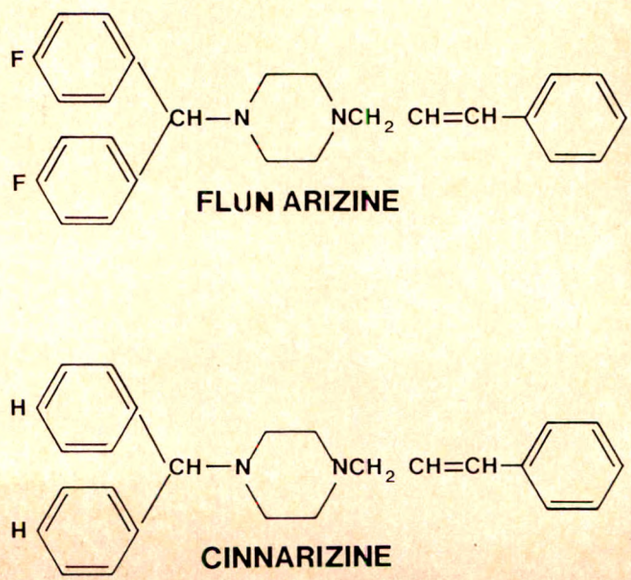

FIGURE 3. Structure of flunarizine and cinnarizine, type 3 of calcium antagonists. These agents have a specificity for vascular tissues.

animals and in patients with varying levels of ventricular function are reasonably well defined; there are modest data for diltiazem and very little for either tiapamil or gallopamil. Although unpublished data have suggested that gallopamil might be extremely effective in terminating supraventricular tachycardias and in controlling chronic stable angina, further data are needed to determine the comparative efficacy of tiapamil and gallopamil on the one hand and verapamil and diltiazem on the other. Neither tiapamil nor gallopamil is currently under investigational evaluation in the United States.

Type 2: The Dihydropyridine Subgroup of Calcium Antagonists

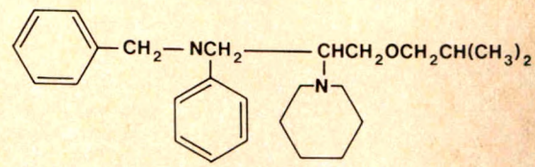
Numerous dihydropyridine derivatives are currently under investigation for the control of a variety of cardiocirculatory disorders, depending upon each drug's presumed specific pharmacologic properties. Of the newer compounds, dihydropyridine derivatives are the most closely related structurally. As a group, the potency of the dihydropyridines is much greater in relation to smooth muscle compared with cardiac muscle. These agents, in vivo, are nearly or completely devoid of clinically significant electrophysiologic properties; their overall hemodynamic effect is dominated by striking peripheral vasodilatation. From the therapeutic standpoint, this may prove of particular value in the control of hypertensive emergencies as well as in the long-term management of essential hypertension, either as single agents or in combination with diuretics, β-adrenergic blocking drugs or other hypotensive agents. It is emphasized that because all of these agents produce marked reflex increases in heart rate and contractility, angina may be aggravated in some patients with coronary artery disease if concomitant sympatholytic agents are not used.

The dihydropyridines may exert tissue selectivity but little data on structure-activity relation are available to document such a predilection.[9] However, it appears that the ester-substituted analogues of nifedipine exhibit a greatly enhanced smooth muscle selectivity relative to nifedipine.[9,10] For example, both niludipine and nisoldipine are more potent than nifedipine as vasodilators, but in vitro all have the same cardiac activity.[9] Substitution at the ester position of the 1,4-dihydropyridine series may be a significant probe for differences in binding site organization or channel function in cardiac and smooth muscle.[11] Whether it might be possible to demonstrate such differences among the smooth muscles of regional vascular beds is at present uncertain, although preliminary data suggest that nimodipine might have selectivity of action in the cerebral vasculature.[10]

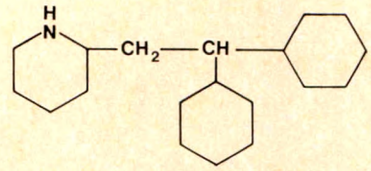
Nimodipine: Nimodipine increases cerebral blood flow[10] with salutary effects in experimental models of subarachnoid hemorrhage, cerebral ischemia and stroke.[11–16] In a double-blind study when the drug was infused intravenously during external carotid to internal carotid bypass surgery in 16 patients,[17] it produced a significant dilatation of pial arteries with resting diameters from 25 to 70 μm. Nimodipine was also found effective in preventing neurologic complications after ruptured cerebral aneurysm.[18] Furthermore, in a prospective, double-blind, randomized, placebo-controlled trial performed in the United States, nimodipine significantly decreased the occurrence of severe neurologic deficits from arterial spasm after subarachnoid hemorrhage. It is also noteworthy that nimodipine (40 mg 3 times a day) had significant beneficial effects on the frequency of migraine attacks and their duration during a 2-month, double-blind, placebo-controlled parallel study in 60 patients;[20] negligible adverse effects were attributable to the drug.

Nitrendipine: Animal studies have documented a pronounced antihypertensive activity for nitrendipine.[21] A single-dose (20 mg orally) study in patients with mild essential hypertension[22,23] showed that the immediate antihypertensive effect was associated with a significant decrease in total peripheral vascular resistance and an increase in heart rate, cardiac output and left ventricular ejection rate in 7 of the 12 study patients who responded to the drug. No postural hypotension developed. In another hemodynamic study,[24] 20 mg orally of nitrendipine, decreased arterial pressure from 225/105 to 177/81 mm Hg within 3 hours as a result of a significant decrease in total peripheral resistance. Clinical trials have suggested that nitrendipine is an effective antihypertensive agent at dosages ranging from 20 to 40 mm/day.[25,26] At the higher dose, there were reports of headache, flushing, tachycardia and palpitations; these effects are consistent with the drug's peripheral vasodilator actions being more marked as the dose is increased.

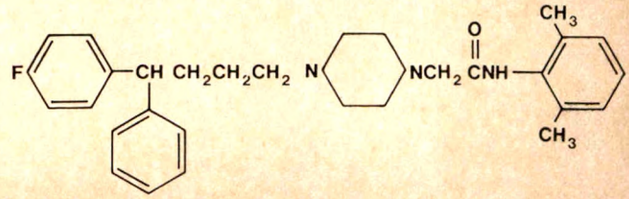
Nisoldipine: Nisoldipine has a preferential action



BEPRIDIL



PERHEXILINE



LIDOFLAZINE

FIGURE 4. Chemical structure of 3 calcium antagonists with a broad pharmacologic profile, type 4 of calcium antagonists. Note striking differences in their structure.

on vascular smooth muscle,[27] but a complete profile of its pharmacodynamic activity has not been delineated. Hemodynamic studies in man after the administration of intravenous nisoldipine have shown a decrease in arterial pressure, total peripheral resistance accompanied by an increase in cardiac output and heart rate and no significant change in the maximum first derivative of left ventricular pressure (dP/dt_{max}).[28]

In hypertensive patients given 5, 10 and 20 mg oral doses, arterial pressure decreased in a dose-dependent manner;[27] this effect was accompanied by an increase in heart rate. The hypotensive effect lasted for 10 hours, indicating a relatively long elimination half-life of the drug. Nisoldipine has no significant electrophysiologic effects in man.[29] In patients with congestive heart failure (New York Heart Association class III), 20 mg of the oral drug improved the hemodynamic status by simultaneously reducing the preload and afterload[30] induced by peripheral vasodilatation with diminished peripheral vascular resistance. Further clinical evaluation of nisoldipine is thus indicated.

Nicardipine: This compound is currently undergoing extensive evaluation in patients with angina pectoris and hypertension in the United States and Europe. In several double-blind, placebo-controlled studies, each using the same protocol design[31] the effects of nicardipine (40 mg) were compared with those of diltiazem (120 mg), nifedipine (20 mg), verapamil (120 mg) and propranolol (80 mg), all administered 3 times a day for 4 weeks. All the drugs increased the duration of treadmill exercise and time to 1 mm ST-segment depression; in the doses used, nicardipine and nifedipine were similar to propranolol, whereas diltiazem and verapamil appeared to be superior. Gheorgiade et al[32] recently provided data clearly documenting the superiority of nicardipine over placebo.

In the first double-blind, placebo-controlled study of nicardipine in patients with angina at rest and coronary spasm, Gelman et al[33] found the drug effective and well-tolerated. The average weekly frequency of anginal attacks and nitroglycerin consumption was decreased in these patients, who had previously been refractory to other calcium blockers.

Several double-blind, parallel, placebo-controlled studies[31,34] have shown that nicardipine significantly decreases blood pressure in hypertensive patients. The hypotensive effects of the drug have been further studied in 18 patients undergoing intraarterial 24-hour ambulatory blood pressure monitoring[35] before and after at least 6 weeks of drug therapy (40 mg twice a day). Patients had moderate-to-severe hypertension (direct blood pressure recording of 160/100 mm Hg for 6 hours on a 24-hour recording) at baseline. Blood pressure was controlled by nicardipine throughout the day, including during exercise and cold challenge. The mean daytime intraarterial blood pressure was significantly decreased by 17/8 mm Hg. However, 4 patients had to be withdrawn from the study because of adverse effects.

Because it appeared to be a potent and long-lasting dilator of cerebral vasculature in animals,[36] the safety and efficacy of nicardipine in the treatment of patients with various cerebral vasculature disorders, especially the sequelae of cerebral hemorrhage and stroke have been investigated in Japan in double-blind clinical trials.[32] It is believed that the drug is effective, but further clinical trials are necessary for confirmation and to determine the relative effectiveness of various calcium antagonists in this setting.

Type 3: The Piperazine Derivatives Flunarizine and Cinnarizine

The properties of the compounds in this type of calcium antagonist, namely cinnarizine and its difluro derivative flunarizine, are highly selective for calcium channels in vascular smooth muscle relative to cardiac muscle.[37] For example, Nakayama and Kasuya[38] showed that the relaxation of potassium-induced contracture of the rabbit basilar artery (ED_{50} 0.12 μmol/liter; relative potency 1) induced by flunarizine was much more than its inhibition of isometric tension of the rabbit papillary muscle (ED_{50} 75 μmol/liter; relative potency 625).

The properties and therapeutic uses of flunarizine were recently reviewed by Holmes et al.[39] Flunarizine has a much longer plasma elimination half-life than does cinnarizine. Most of the therapeutic trials with flunarizine involved the prophylaxis of migraine, occlusive peripheral vascular disease and vertigo of central and peripheral origin. The data from placebo-controlled studies indicate that flunarizine is more effective than placebo in these conditions when evaluated by subjective and objective criteria.[40–50] Prophylactic protection of flunarizine has been reported in patients with migraine;[43–45] 1 double-blind study[46] has indicated that flunarizine suppressed the severity of migraine attacks and significantly reduced the number of episodes. Symptoms of vertebrobasilar insufficiency were found improved in 20 patients given flunarizine, 20 mg/day for 8 weeks, in another study.[47] Objective parameters were measured using electroencephalography, electronystagmography and Doppler sonography; results correlated well with symptomatic improvement. There was a subsequent double-blind, placebo-controlled, crossover trial using 10 mg/day of flunarizine in 41 patients with vertigo.[48] After a 4-week run-in period, 40 responders were randomized to either continued treatment or placebo. After 6 weeks, the patients were crossed-over to the alternative therapy. The administration of placebo significantly worsened the patients' condition. Flunarizine did not significantly decrease tinnitus.

Another study showed that flunarizine (10 to 20 mg/day for 6 months) improved Doppler flowmeter readings and increased independent mobility in patients with arteriopathies of the lower extremities. In 4 double-blind, placebo-controlled studies in patients with venous insufficiency (varicose veins and venous ulcers), flunarizine, 10 mg/day, significantly improved symptoms, reduced the circumference of swollen legs and ankles and increased the speed of healing of venous ulcers in the legs.[50]

These preliminary data with the piperazine derivatives suggest new and useful pharmacologic approaches to the control of several circulatory disorders, but the precise role of these compounds in therapy must await results of further stringently controlled comparative studies.

Type 4: Calcium Antagonists with Complex Pharmacologic Profiles

The fourth group of pharmacologic agents may be categorized as calcium antagonists that have a selectivity of action either for vascular tissues (for example, lidoflazine) or (in the case of perhexiline[51–53] and bepridil[54]) for both cardiac and smooth muscle, while they also have the propensity to block the fast sodium channel in the heart to a variable degree. Some of these agents have still other electrophysiologic properties. These agents are not only heterogeneous chemically but, by virtue of their overall complex pharmacologic properties, they may exert a somewhat different spectrum of therapeutic effects. This pertains particularly to their cardiac electrophysiologic actions and to the control of cardiac arrhythmias.

Lidoflazine: Like flunarizine and cinnarizine, lidoflazine is a piperazine derivative. With them, it shares the property of relaxing vascular smooth muscle in the coronary arteries and peripheral vessels by competitively blocking calcium transport. Thus, it can be regarded as a calcium antagonist even though it does not inhibit the slow channel in cardiac tissues. However, unlike flunarizine and cinnarizine, lidoflazine blocks the fast sodium channel in cardiac muscle and lengthens repolarization. In vitro data indicate that, in relatively small concentrations under voltage clamp conditions, the drug does not block the myocardial slow channel.[54] Thus, even in high doses lidoflazine has no significant negative inotropic effect in patients with angina pectoris.[55,56] Lidoflazine does not alter heart rate at rest, but it does increase the duration of treadmill exercise in patients with angina pectoris while delaying the onset of ST-segment depression.[56] Lidoflazine is a potent coronary dilator[57] and has the propensity to ameliorate perfusion deficits induced by treadmill exercise in patients with coronary artery disease.[56] The available data suggest that the antianginal effects of the drug in various myocardial ischemic syndromes are likely to be similar to those of other calcium antagonists.

Scant information is available regarding the electrophysiologic effects of lidoflazine in man. However, it has been shown to prolong the QTc interval in the surface electrocardiogram in a clinical study.[58] The properties of the compound appear to be similar to quinidine and quinidine-like drugs with potential for antiarrhythmic as well as arrhythmogenic effects. Neither of these features has so far been studied in detail, although anecdotal cases of torsade de pointes accompanied by syncope have been described in association with the therapeutic use of lidoflazine.

Bepridil: This is perhaps the most promising of the type 4 agents. Unlike other calcium antagonists, bepridil has a long elimination half-life (almost 40 hours).

Electrophysiologically, bepridil is unusual: it blocks the slow calcium channel in the heart,[59] while it inhibits the fast channel and lengthens the repolarization phase of the cardiac action potential in all myocardial tissues with the possible exception of Purkinje fibers. These data are consistent with preliminary clinical observations;[60] intravenous bepridil prolonged the effective refractory period of atria, ventricles and AV node, while lengthening the Wenckebach cycle of the AV node during rapid atrial pacing. The spontaneous sinus cycle length was not significantly altered nor was the sinus nodal recovery time, although patients with sick sinus disease were not studied. The AH interval was prolonged with a trend toward an increase in the HV interval during electrophysiologic studies.

The available data suggest that unlike most other calcium antagonists, bepridil is likely to be effective in ventricular and supraventricular tachyarrhyhthmias, although the relative potencies of the compound in these 2 groups of dysrhythmias remain to be determined. Preliminary data on the prevention of ventricular tachycardia induced by progammed electrical stimulation of the heart are conflicting;[61] data on the suppression of premature ventricular contraction also need further documentation. It should be emphasized that because the overall properties of bepridil in ventricular muscle resemble those of quinidine, the compound may produce torsade de pointes in toxic doses or when it is used in the setting of hypokalemia or hypomagnesemia.

When bepridil was given intravenously to dogs, coronary vascular resistance decreased and coronary blood flow increased.[62] In patients with chronic stable angina,[63] bepridil exerts significant antianginal efficacy with respect to reduction in nitroglycerin consumption and anginal frequency. Narahara et al,[64] in a single-blind, 20-patient, placebo-controlled study, (in 13 with resting and exercise radionuclide ventriculography) showed that bepridil (up to 300 mg/day orally), significantly decreased anginal frequency and increased total work performed on upright bicycle. The exercise duration increased from 5.3 to 6.6 minutes ($p < 0.005$) and the expected deterioration in left ventricular function induced by exercise was prevented. A recent multicenter study has further documented the antianginal efficacy of bepridil in chronic stable angina[65] and a smaller study[66] has shown that the drug has the capability to reduce the duration of painless as well as pain-related ischemia in patients with chronic stable angina studied by ambulatory Holter recordings analyzed by the compact analogue technique.[67]

At present, the comparative antianginal and antiischemic efficacy of bepridil and other calcium antagonists is not well defined, nor are the issues of the safety and efficacy of a bepridil–β-blocker combination resolved. However, the available data indicate that bepridil may develop into a calcium antagonist with a wide spectrum of use. Its pharmacologic properties and therapeutic potential compared with its adverse effect profile (that is, its arrhythmogenic propensity) should be further evaluated.

In summary, we have reviewed data on the newer calcium antagonists that hold promise in cardiovascular therapeutics and offer several conclusions. First, although the conceptual framework for characterizing calcium antagonists postulated by Fleckenstein provided an important impetus for the development of calcium antagonist therapy, refinements in his original concept are now needed to allow for a systematic understanding of the newer compounds. Second, classification of the available compounds based on an understanding of their specificity for cardiac and smooth muscle appears to have some clinical relevance. However, structure-activity relations within groups may reveal further differences that might be of therapeutic value. Third, the fact that there are marked structural differences among different calcium antagonists, old and new, means each agent needs to be studied experimentally and clinically to define its precise role in human therapeutics. Finally, based on the available information, it is reasonable to assume that further advances—in the development of both tissue-selective calcium-channel antagonists and calcium-channel antagonists with a broad pharmacologic profile and therapeutic spectrum of activity—are imminent.

Acknowledgment: We thank Lawrence Kimble for secretarial assistance in the preparation of this manuscript, and the medical media department of Wadsworth VA Hospital for assistance with the illustrations.

Angina Protection with Benefits for a Lifetime

ONCE-DAILY CONTROL WITH HEART-SAVING BENEFITS

By reducing heart rate and cardiac contractility, INDERAL LA helps protect the heart from the potentially serious and debilitating consequences of ischemia. A highly effective antianginal agent for around-the-clock control of symptoms, INDERAL LA also provides cardiovascular protection for a sense of security in the years ahead.

PROTECTION AND EXPERIENCE NO CALCIUM BLOCKER CAN MATCH

Unlike calcium blockers, INDERAL LA—either alone or with a nitrate—is recommended for early treatment of angina in the majority of patients. Equally important, INDERAL LA delivers the proven performance and safety profile of INDERAL tablets—confirmed by millions of patients during 16 years of clinical use.

START WITH 80 MG ONCE DAILY

Dosage may be increased to 160 mg once daily, as needed, to achieve optimal control. INDERAL LA should not be used in congestive heart failure, sinus bradycardia, cardiogenic shock, heart block greater than first degree, and bronchial asthma. Please see next page for further details and brief summary of prescribing information.

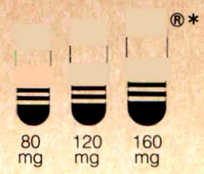
ONCE-DAILY

INDERAL® LA

(PROPRANOLOL HCl) LONG ACTING CAPSULES



BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
INDERAL® LA brand of propranolol hydrochloride **(Long Acting Capsules)**
DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg, and 160 mg capsules.
CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the pial vessels of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.
INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migrai..e: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.
CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock; 2) sinus bradycardia and greater than first degree block; 3) bronchial asthma; 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.
WARNINGS. CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)— PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.
PRECAUTIONS. *General:* Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.
DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood-pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.
PEDIATRIC DOSAGE—At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

*The appearance of INDERAL LA capsules is a registered trademark of Ayerst Laboratories.

Mansfield's life saving tips for the cardiologist.

ATRI-PACE FLARE.™ EP STYLECTRODE.™ ATRI-PACE J and VENTRI-PACE STYLECTRODES.™ PERICARDIOCENTESIS. Cardiovascular catheter tips to remember.

The science of cardiology is changing quickly. And that's as it should be. Because modern technology has no higher goal than saving human lives.

At Mansfield Scientific, we understand the needs of today's cardiologist. We develop advanced catheters and electronic systems and put them to work for you.

For example, our ATRI-PACE FLARE features a unique flared-tip design that assures minimum thresholds and maximum stability against the atrial endocardium.

Our EP STYLECTRODE offers the latest in electrophysiology catheter design by including a movable integral stylet for varying tip stiffness and tip curve configuration.

Our ATRI-PACE J and VENTRI-PACE STYLECTRODES offer the same tip feature for easy placement, combined with excellent directional control and stability.

Our PERICARDIOCENTESIS catheter has a flexible tip with large lumens for rapid drainage.

So for your cardiovascular catheter needs, call Mansfield Scientific. When your patients' lives are at risk, it's a tip you can trust.

PERFORMANCE STRESS

SYSTEM Q™ BY QUINTON

There are times when only the best will do: When you want to stress test *your* way—without compromise. When doctors share a stress system. When you need flexibility to perform different procedures.

That's when you need the high performance capabilities of SYSTEM Q by Quinton—the most advanced stress test system ever created.

Ultimate flexibility.

No other system gives you more control over a stress test. You program the recorder, screen displays, treadmill and even the ECG analysis to meet your specific requirements.

And your colleagues can do the same. SYSTEM Q can store up to four programmed test procedures, each customized to meet the needs of a different physician. (Or a different test.) It's the closest you'll come to a separate system to meet the needs of every doctor.

Superior diagnostic information.

SYSTEM Q gives you more data, more accurately than ever before possible: An averaged beat final report, with computed ST parameters. The most sophisticated QRS detection algorithms ever developed. A more precise calculation of ST parameters. A more stable heartrate indication. And more.

Quinton family of stress testing equipment

When you need high powered capabilities, get the high performance stress test system: SYSTEM Q by Quinton. (It performs well on the bottom line, too.) For more information about the Quinton family of stress testing equipment, call or write us at 2121 Terry Ave., Seattle, WA 98121. 1-800-426-0347. Telex 328840.

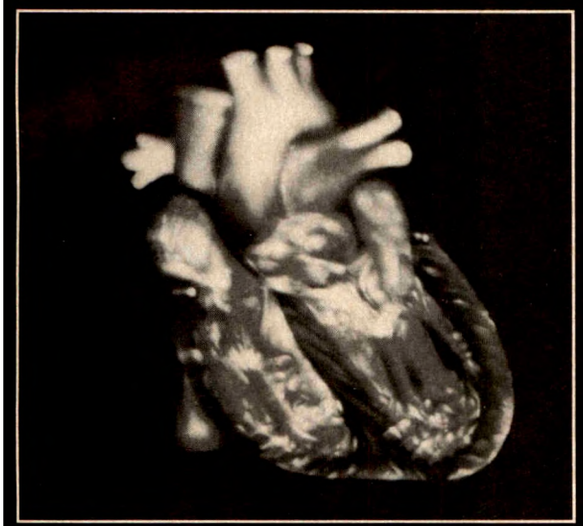
CORGARD®
(nadolol tablets)

40 mg, 80 mg, 120 mg, and 160 mg
easy-to-break scored tablets

ONCE A DAY FOR ANGINA PECTORIS



)RGARD® TABLETS
dolol Tablets

SCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor cking agent.

)NTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first gree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

ARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component pporting circulatory function in congestive heart failure, and its inhibition by beta- ckade may precipitate more severe failure. Although beta-blockers should be avoided overt congestive heart failure, if necessary, they can be used with caution in patients h a history of failure who are well-compensated, usually with digitalis and diuretics. a-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart scle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of a-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or mptom of heart failure, digitalize and/or give diuretics, and closely observe response, discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — TIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE TA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation duced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to ex stimuli and may increase risks of general anesthesia and surgical procedures, ulting in protracted hypotension or low cardiac output, it has generally been suggested t such therapy should be withdrawn several days prior to surgery. Recognition of the reased sensitivity to catecholamines of patients recently withdrawn from beta-blocker rapy, however, has made this recommendation controversial. If possible, withdraw a-blockers well before surgery takes place. In emergency surgery, inform the esthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists h as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of dolol. Difficulty in restarting and maintaining the heart beat has also been reported h beta-adrenergic receptor blocking agents.

ance of premonitory signs and symptoms (e.g., tachycardia and bl of acute hypoglycemia. This is especially important with labile di also reduces release of insulin in response to hyperglycemia; necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certa tachycardia) of hyperthyroidism. To avoid abrupt withdraw blockade which might precipitate a thyroid storm, carefully manag developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Us in presence of either of these conditions (see DOSAGE AND ADM of package insert).

Information for Patients — Warn patients, especially th coronary artery insufficiency, against interruption or discontinuat physician's advice. Although cardiac failure rarely occurs in prop advise patients being treated with beta-adrenergic blocking agents first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., re additive effect when given with beta-blocking agents. When t nadolol plus a catecholamine-depleting agent, carefully observe tension and/or excessive bradycardia which may produce vertigo hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility - toxicologic studies in mice, rats, and dogs, nadolol did not pro effects. In 2-year oral carcinogenic studies in rats and mice, na neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evi fetotoxicity was found in rabbits (but not in rats or hamsters) at dose (on a mg/kg basis) than maximum indicated human dose; no tera seen in any of these species. There are no well-controlled studies therefore, use nadolol in pregnant women only if potential benefit to the fetus.

Nursing Mothers — It is not known whether this drug is exc Because many drugs are excreted in human milk, exercise cau administered to a nursing woman. Animal studies showed that n milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have no

ADVERSE REACTIONS: Most adverse effects have been mild a rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than occurs commonly, and heart rates below 40 beats per minute bradycardia were seen in about 2 of 100 patients. Symptoms o insufficiency, usually of the Raynaud type, have occurred in ap patients. Cardiac failure, hypotension, and rhythm/conduction di occurred in about 1 of 100 patients. Single instances of first degree a block have been reported; intensification of AV block is a known (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTION

System — Dizziness or fatigue reported in approximately 2 of 100 sedation, and change in behavior reported in approximately

Respiratory — Bronchospasm reported in approximately 1 CONTRAINDICATIONS and WARNINGS). **Gastrointestinal -** abdominal discomfort, constipation, vomiting, indigestion, an flatulence each reported in 1 to 5 of 1000 patients. **Miscellan** following reported in 1 to 5 of 1000 patients: rash; pruritus; headach skin; impotence or decreased libido; facial swelling; weight gain; s nasal stuffiness; sweating; tinnitus; blurred vision. Although relatio not clear, sleep disturbances have been reported. The oculomuc associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects rep adrenergic blocking agents have not been reported with nad considered potential adverse effects of nadolol. **Central Nervous** mental depression progressing to catatonia; visual disturbances; ha reversible syndrome characterized by disorientation for time a memory loss, emotional lability with slightly clouded sensorium; d on neuropsychometrics. **Gastrointestinal —** mesenteric arterial colitis. **Hematologic —** agranulocytosis; thrombocytopenic or r purpura. **Allergic —** fever combined with aching and sore t respiratory distress. **Miscellaneous —** reversible alopecia; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circula In addition to gastric lavage, employ the following measure determining duration of corrective therapy, take note of long durati

Excessive Bradycardia — Administer atropine (0.25 to 1. response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diureti that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent ar derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZE

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradu 80 mg increments at 3 to 7 day intervals until optimum clinical res slowing of the heart rate; usual maintenance dose is 80 to 240 m respond to 160 mg or less daily). If treatment is to be disconti gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually ir increments until optimum blood pressure reduction is achieved; us is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 in bottles of 100 and 1000 tablets and in Unimatic® unit-dose pac

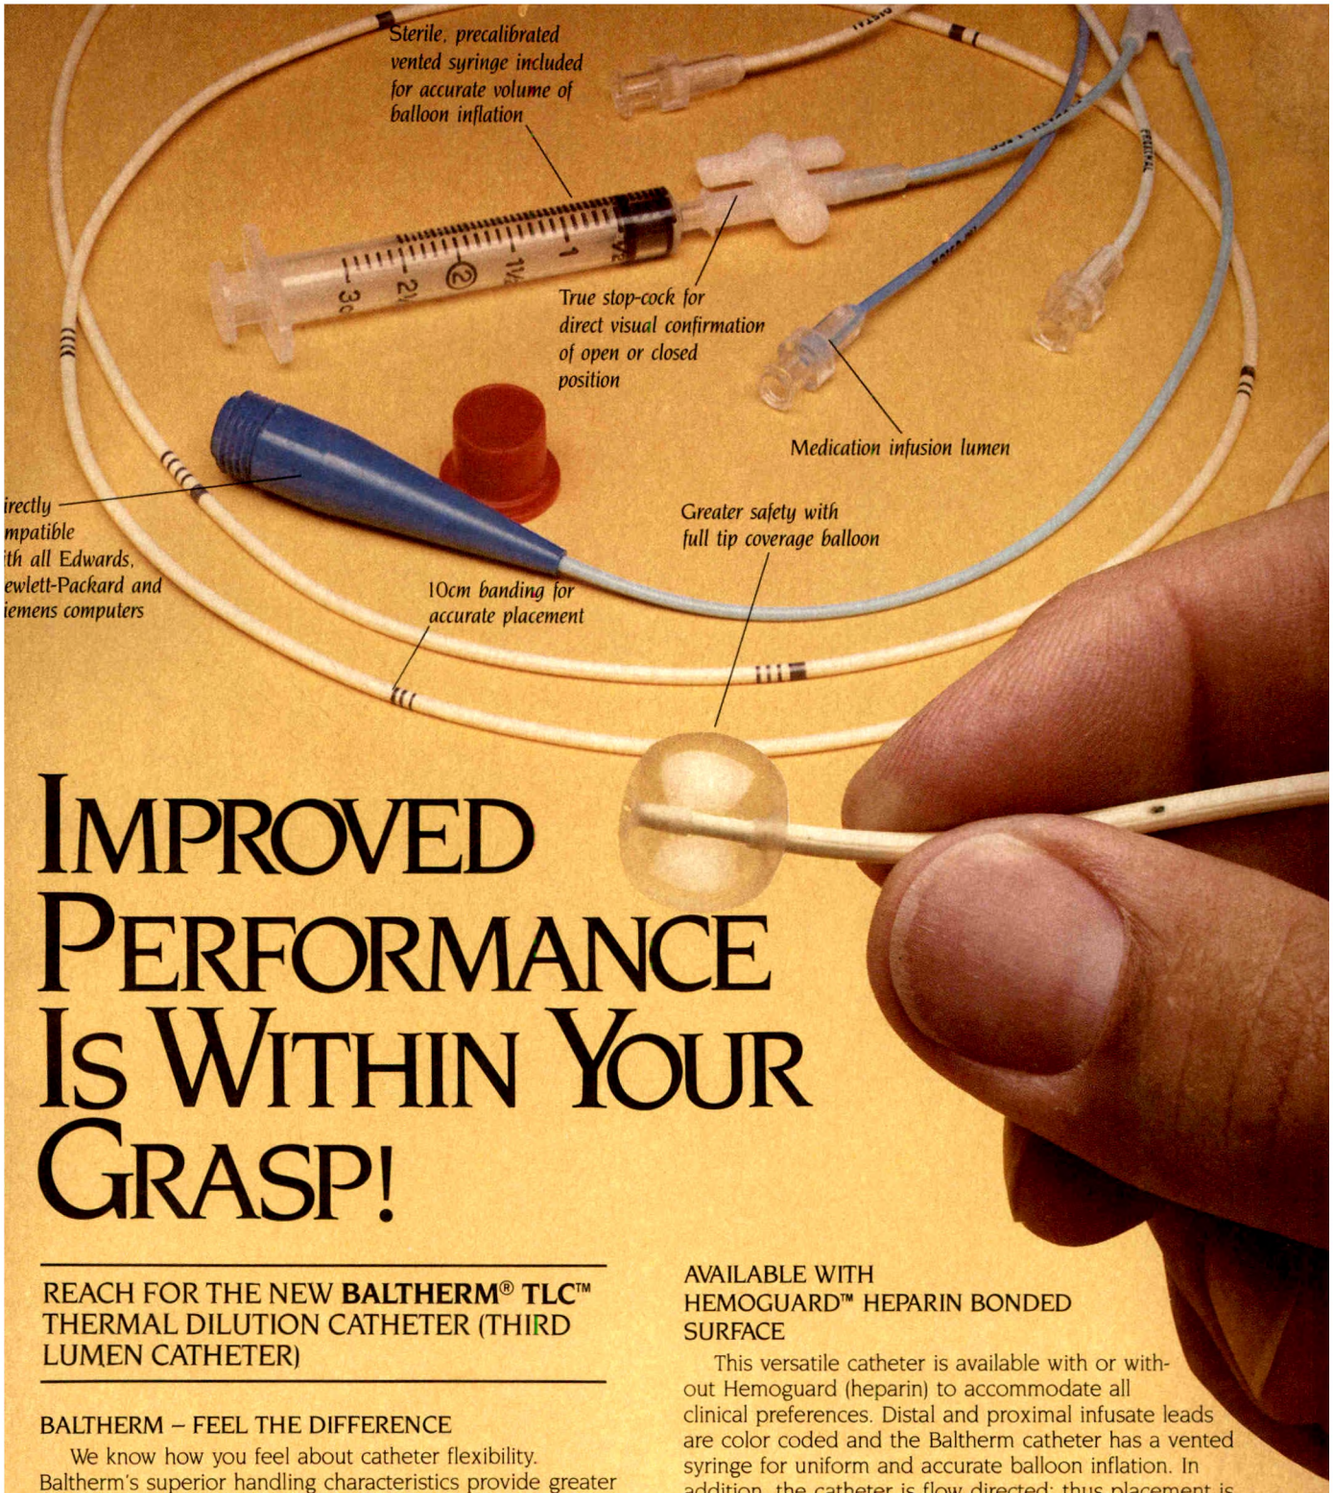
INSTRUCTIONS TO AUTHORS on page 498



IMPROVED PERFORMANCE IS WITHIN YOUR GRASP!

REACH FOR THE NEW **BALTHERM® TLC™** THERMAL DILUTION CATHETER (THIRD LUMEN CATHETER)

BALTHERM – FEEL THE DIFFERENCE

We know how you feel about catheter flexibility. Baltherm's superior handling characteristics provide greater sensitivity and give you a better feel for the catheter's position throughout the placement procedure. Not only does it enable you to do frequent cardiac output measurements, but to continually administer lifesaving solutions directly into the central circulation . . . through a single venipuncture site.

COMPATIBLE WITH OTHER SYSTEMS

Model No. 73-6367H and 73-6367 are compatible with the Elecath Cardiac Output Computer.

Model No. 73-9367H and 73-9367 are precalibrated and fully compatible with Edwards, Hewlett Packard, and Siemens Cardiac Output Computers.

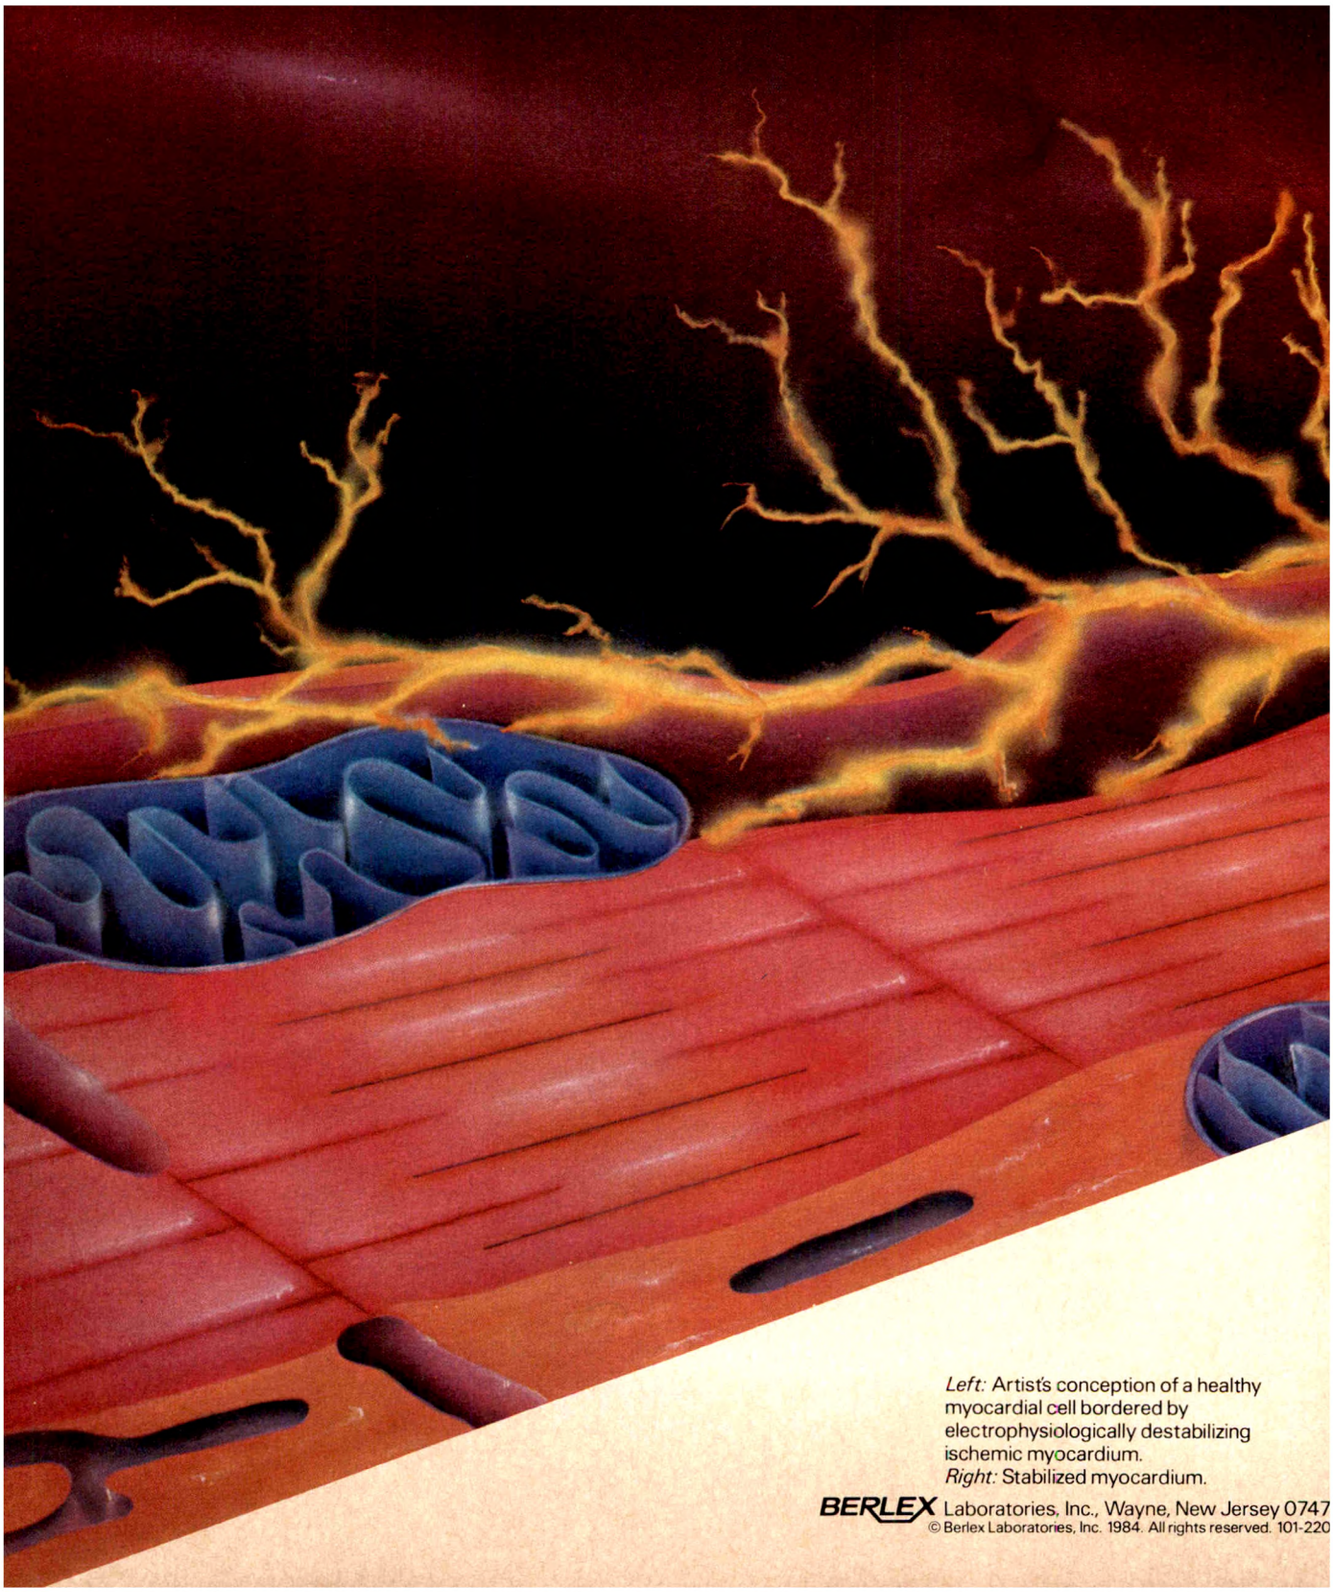
AVAILABLE WITH HEMOGUARD™ HEPARIN BONDED SURFACE

This versatile catheter is available with or without Hemoguard (heparin) to accommodate all clinical preferences. Distal and proximal infusate leads are color coded and the Baltherm catheter has a vented syringe for uniform and accurate balloon inflation. In addition, the catheter is flow directed; thus placement is accomplished quickly and accurately.

The next time you specify a thermal dilution catheter, reach for BALTHERM TLC (Third Lumen Catheter). For your standard thermal dilution needs, Baltherm models 73-9067, 73-6067, and 73-4067 are available without the extra infusion lumen. Electro-Catheter Corporation, 2100 Felver Court, Rahway, New Jersey 07065 800-526-4243; In New Jersey: 201-382-5600 TELEX: 138171

ELECATH®

INNOVATIVE CARDIOVASCULAR TECHNOLOGY



Left: Artist's conception of a healthy myocardial cell bordered by electrophysiologically destabilizing ischemic myocardium.
Right: Stabilized myocardium.

Working to Control Arrhythmias

The Stabilizer:

QUINAGLUTE® DURA-TABS®

(quinidine gluconate) SUSTAINED-RELEASE TABLETS 324 mg

Stable plasma levels: a factor in maintaining stable cardiac rhythm

Easy-to-remember q12h dosage* promotes compliance

Fewer GI side effects than quinidine sulfate†

*Some patients may require more frequent (TID) dosing.

†Podrid PJ: *Patient Care* 1981;15:100-132.

Please turn page for brief summary of prescribing information.

INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock)
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.
Information for Patients: As with all solid oral medications, Quinaglute (quinidine gluconate) Dura-Tabs (sustained-release tablets) should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.
See package insert for full information.

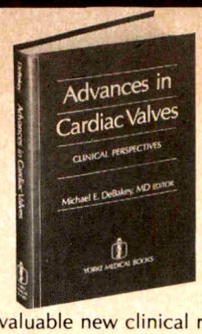
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD
0-914316-40-0, 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of the information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

CORONARY HEART DISEASE

251 **Medically Directed At-Home Rehabilitation Soon After Clinically Uncomplicated Acute Myocardial Infarction: A New Model for Patient Care**

ROBERT F. DeBUSK, WILLIAM L. HASKELL, NANCY H. MILLER, KATHY BERRA, and CRAIG BARR TAYLOR, *In cooperation with* WALTER E. BERGER III *and* HENRY LEW

Medically directed at-home rehabilitation was compared with group rehabilitation that began 3 weeks after clinically uncomplicated acute myocardial infarction (AMI) in 127 men, mean age 53 ± 7 years. Between 3 and 26 weeks after AMI, adherence to individually prescribed exercise was equally high (≥71%), the increase in functional capacity equally large (1.8 ± 1.0 METs) and nonfatal reinfarction and dropout rates equally low (both ≤3%). No testing- or training-related complications occurred in either group. Medically directed at-home rehabilitation has the potential to increase the availability and to decrease the cost of rehabilitating low-risk survivors of AMI.

258 **Effect of Beta-Adrenergic Blockade on the Results of Exercise Testing Related to the Extent of Coronary Artery Disease**

STEPHEN W.-C. HO, MICHAEL J. McCOMISH, and ROGER R. TAYLOR

Maximal treadmill exercise testing was carried out in 50 patients with angiographically documented coronary artery disease in the presence and absence of β-adrenoceptor blockade. This treatment increased the duration of exercise, delayed the onset of angina or suppressed its occurrence and, hence, altered the limiting symptom, delayed the onset of ST-segment depression and reduced maximal ST depression. Inconclusive tests (absence of ST-segment changes and failure to reach target heart rate) were increased. Without β blockade, there was a significantly shorter duration of exercise in those with left main (LM) disease, and 3-vessel or LM disease were infrequent in the absence of limitation by angina, features abolished by β blockade. It is concluded that β blockade obscures the diagnostic and prognostic interpretation of exercise testing and impairs the ability to select those likely to have extensive coronary obstructive disease.

263 **Early Exercise Training in Patients Older than Age 65 Years Compared with that in Younger Patients After Acute Myocardial Infarction or Coronary Artery Bypass Grafting**

MARK A. WILLIAMS, CARL M. MARESH, DENNIS J. ESTERBROOKS, JAMES J. HARBRECHT, and MICHAEL H. SKETCH

To evaluate potential benefits that elderly cardiac patients might gain from early exercise programs, 361 cardiac patients were studied. Seventy-six patients were aged 65 years or older. All patients participated in a 12-week exercise program after an acute myocardial infarction or coronary artery bypass grafting. Comparison of data before and after exercise revealed that elderly patients had significant decrease in body weight, percent body fat, resting heart rate, submaximal average double product, and submaximal average rating of perceived exertion. Maximal achieved heart rate and METs significantly increased. Magnitudes of change seen in the elderly were similar to those seen in younger patients. These results suggest that the benefits of an early exercise program in younger patients may also be expected in elderly patients.

267 **Early Positive Exercise Test and Extensive Coronary Disease: Effect of Antianginal Therapy**

JHULAN MUKHARJI, MARK KREMERS, KIRK LIPSCOMB, and C. GUNNAR BLOMQVIST

To examine the effect of antianginal therapy on the incidence of an early positive exercise response, 57 men with stable angina pectoris underwent bicycle ergometry before and after treatment with a calcium-blocking agent and long-acting nitrates. A 63% reduction in early positive responses was noted after therapy. In 24 pa-

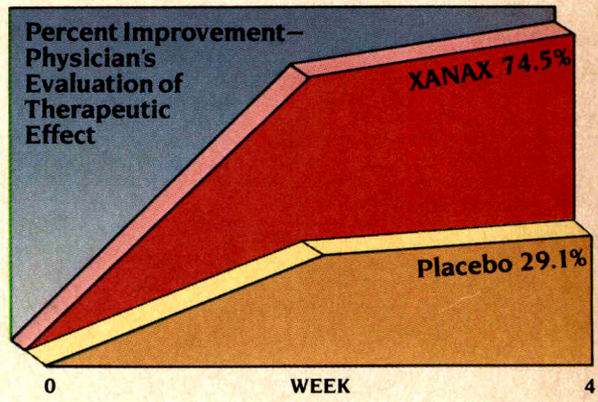
Many anxious patients
have cardiovascular
symptoms of anxiety.

Xanax rapidly relieves anxiety...

In double-blind, four-week, clinical trials in 976 patients with moderate to severe anxiety, therapy with XANAX was compared with placebo.[1]

XANAX was significantly more effective ($p<0.001$) than placebo in relieving the anxiety, with over half of the patients showing marked to moderate improvement by the first evaluation period (one week).



...including cardiovascular symptoms of anxiety...

Most patients in the study had cardiovascular symptoms even though cardiovascular disease was ruled out. XANAX was shown to effectively relieve anxiety including the accompanying cardiovascular symptoms.

...and depressive symptoms of anxiety.

Over 70% of these patients experienced moderate to severe depressed mood. XANAX was shown to be significantly more effective ($p<0.014$) than placebo in improving depressed mood.

1. Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. J *Clin Psychiatry* 1981;42:347-351.

Xanax® 0.5 mg Tablets

alprazolam C IV

Upjohn

The Upjohn Company • Kalamazoo, Michigan 49001 USA

Please see next page for brief summary of prescribing information. © 1984 The Upjohn Company

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

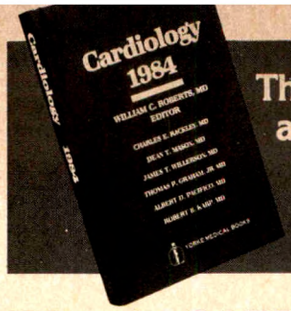
J-4392 October 1984



The most important and best read annual publication on cardiology.

What is CARDIOLOGY 1984?

- ☐ The fourth in an annual series to be published in the summer each year — over 750 papers
- ☐ A review of the year's newest and most important developments in cardiology
- ☐ A **multidisciplinary** approach to clinical and applied research based on an exhaustive search of the year's literature
- ☐ A unique, cohesive summary of the state-of-the-art, **written,** not edited, by those making outstanding developments in the field
- ☐ A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1984 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

☐ William C. Roberts, MD Editor ☐ Charles E. Rackley, MD ☐ Dean T. Mason, MD ☐ James T. Willerson, MD ☐ Thomas P. Graham, Jr, MD ☐ Albert D. Pacifico, MD ☐ Robert B. Karp, MD

These seven leaders in their respective fields of cardiology have reviewed the year's literature in their own areas and have worked together coordinating their individual efforts into a cohesive whole.

ISBN 0-914316-42-7, 512 pages, 117 illus., June'84

tients who underwent coronary arteriography, the sensitivity and specificity of an early positive response in predicting 3-vessel and left main disease changed from 92% and 58% before to 42% and 75% after therapy. The positive and negative predictive values changed from 69% and 88% before to 63% and 63% after therapy. It is concluded that antianginal therapy reduces the usefulness of an early positive exercise response in screening for extensive coronary disease.

271 Improved Accuracy of the Exercise Electrocardiogram: Identification of Three-Vessel Coronary Disease in Stable Angina Pectoris by Analysis of Peak Rate-Related Changes in ST Segments

PETER M. OKIN, PAUL KLIGFIELD, OLIVIER AMEISEN, HARVEY L. GOLDBERG, and JEFFREY S. BORER

To assess the applicability of the rate-related change in ST-segment depression (ST/HR slope) for the identification of 3-vessel coronary artery disease (CAD), 50 patients in whom exercise electrocardiography and coronary cineangiography had been performed for suspected CAD were retrospectively evaluated. Standard electrocardiographic criteria ($\geq$1 mm horizontal or downsloping ST depression) identified 3-vessel CAD with a sensitivity of 78%, specificity of 56% and positive predictive value of only 50%. Peak ST/HR slope criteria ($\geq$6.0 μV/beat/min) identified 3-vessel CAD with a sensitivity of 78%, specificity of 97% and positive predictive value of 93%. Overall test accuracy using measured peak ST/HR slope was 90% compared with 64% for standard ST-depression criteria. It is concluded that analysis of the peak ST/HR slope can greatly improve the diagnostic accuracy of exercise electrocardiography, and that further prospective study of this method is indicated.

277 Effect of Coffee on Exercise-Induced Angina Pectoris Due to Coronary Artery Disease in Habitual Coffee Drinkers

KENNETH M. PITERS, ANTONIO COLOMBO, HAROLD G. OLSON, and SAMUEL M. BUTMAN

The acute effects of coffee on exercise-induced angina pectoris were studied in 17 patients with coronary artery disease using a double-blind treadmill protocol. Both 1 and 2 cups of caffeinated coffee increased the exercise duration until onset of angina (8 and 12%, respectively, $p < 0.05$), whereas 2 cups of decaffeinated coffee had no effect. The exercise duration until 0.1 mV of ST-segment depression, as well as the heart rate, blood pressure and double product at angina and at 0.1 mV of ST-segment depression were similar after ingestion of caffeinated or decaffeinated coffee. Serum caffeine levels indicated adequate absorption of caffeine. The acute ingestion of 1 to 2 cups of caffeinated coffee had no deleterious effect on exercise-induced angina in patients with coronary artery disease.

281 Propranolol-Verapamil Versus Propranolol-Nifedipine in Patients with Severe Angina Pectoris of Effort: A Randomized, Double-Blind, Crossover Study

MICHAEL D. WINNIFORD, KAY L. FULTON, JAMES R. CORBETT, CHARLES H. CROFT, and L. DAVID HILLIS

Sixteen patients with continuing angina and a positive exercise tolerance test despite therapy with propranolol were maintained on a constant dose of propranolol and, in addition, received verapamil (360 mg/day) and nifedipine (60 mg/day) for 3 weeks each in a double-blind, randomized fashion. In comparison with propranolol alone, a propranolol-verapamil combination reduced anginal frequency, nitroglycerin usage, and the magnitude of ST-segment depression during exercise, whereas a propranolol-nifedipine combination exerted no significant effect on anginal frequency or nitroglycerin usage. Thus, in patients with severe angina of effort who took propranolol alone, the addition of verapamil was more effective than the addition of nifedipine.

286 Hemodynamic and Metabolic Effects of Diltiazem During Coronary Sinus Pacing with Particular Reference to Left Ventricular Ejection Fraction

MARTIN A. JOSEPHSON, JAMES HOPKINS, and BRAMAH N. SINGH

Fifteen patients with coronary artery disease undergoing cardiac catheterization were studied before and after intravenous diltiazem, 0.165 to 0.25 mg/kg. Hemodynamic variables, metabolic measurements and left ventricular ejection fractions were obtained at rest and during coronary sinus pacing before and during diltiazem administration. At rest, systemic resistance was reduced by 22% ($p < 0.01$) and mean arterial pressure by 12% ($p < 0.01$); cardiac index increased from 2.4 $\pm$ 0.4 to 2.6 $\pm$ 0.4 liters/min/m^2 ($p < 0.01$) with no significant change in heart rate. The mean pulmonary artery pressure increased from 17 $\pm$ 2 to 19 $\pm$ 3 mm Hg ($p < 0.01$), but other hemodynamic variables were not affected. Diltiazem given during pacing reduced mean aortic pressure (112 $\pm$ 15 to 104 $\pm$ 15 mm Hg, $p < 0.05$) but other hemodynamic variables were not affected significantly. Diltiazem did not affect left ventricular ejection fraction at rest, but significantly lessened the decrease in ejection fraction (16 vs 8%, $p < 0.01$) that occurred during pacing.

To reduce the risk of cardiovascular mortality and reinfarction in many stabilized patients who have survived the acute phase of an MI

Results from a major clinical study[1]

Reduces sudden death by 44.6% (death within 24 hours)

Reduces instantaneous death by 71.4% (death occurring within a few seconds)

Reduces overall mortality by 39.4%

Reduces reinfarction by 28.4%

It is recommended that treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if BLOCADREN is initiated later.

1. The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. *304(14)*:801-807, April 2, 1981.

UNIVERSITY MEDICINE LIBRARY

BLOCADREN is contraindicated in patients with bronchial asthma, a history of bronchial asthma, or severe chronic obstructive pulmonary disease (see below); sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated. In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after abrupt discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

In patients with nonallergic bronchospasm or with a history of nonallergic bronchospasm (e.g., chronic bronchitis, emphysema), BLOCADREN should be administered with caution.

BLOCADREN®
(TIMOLOL MALEATE) MSD

CONTRAINDICATIONS:

BLOCADREN is contraindicated in patients with bronchial asthma, a history of bronchial asthma, or severe chronic obstructive pulmonary disease (see WARNINGS); sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal – Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm: In patients with nonallergic bronchospasm or with a history of nonallergic bronchospasm (e.g., chronic bronchitis, emphysema), BLOCADREN should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol (see OVERDOSAGE).

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Muscle Weakness: Beta-adrenergic blockade has been reported to potentiate muscle weakness consistent with certain myasthenic symptoms (e.g., diplopia, ptosis, and generalized weakness). Timolol has been reported rarely to increase muscle weakness in some patients with myasthenic symptoms.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN® (Timolol Maleate, MSD) is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Blunting of the antihypertensive effect of beta-adrenoceptor blocking agents by nonsteroidal anti-inflammatory drugs has been reported. When using these agents concomitantly, patients should be observed carefully to confirm that the desired therapeutic effect has been obtained.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5,000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays), but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed, nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Reproduction and fertility studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy – Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
SKIN		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure – Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema – Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.
‡Only principal reason for withdrawal in each patient is listed.
These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole:* extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular:* cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive:* gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Hematologic:* nonthrombocytopenic purpura; *Endocrine:* hyperglycemia, hypoglycemia; *Skin:* rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal:* arthralgia; *Nervous System:* local weakness; *Psychiatric:* depression, nightmares, somnolence, insomnia, nervousness, diminished concentration, hallucinations; *Respiratory:* cough; *Special Senses:* visual disturbances, diplopia, ptosis, dry eyes; *Urogenital:* impotence, urination difficulties.

There have been reports of retroperitoneal fibrosis in patients receiving timolol maleate and in patients receiving other beta-adrenergic blocking agents. A causal relationship between this condition and therapy with beta-adrenergic blocking agents has not been established.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN® (Timolol Maleate, MSD), but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System:* reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular:* intensification of AV block (see CONTRAINDICATIONS); *Digestive:* mesenteric arterial thrombosis, ischemic colitis; *Hematologic:* agranulocytosis, thrombocytopenic purpura; *Allergic:* erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous:* reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations. 183 (DC7117616)

291 Familial Aggregation and Early Expression of Hyperapobetalipoproteinemia

ALLAN SNIDERMAN, BABIE TENG, JACQUES GENEST, KATHERINE CIANFLONE, SHOLOM WACHOLDER, and PETER KWITEROVICH Jr.

Hyperapobetalipoproteinemia is the combination of a normal or near normal low-density lipoprotein (LDL) cholesterol level in the face of an elevated LDL apoB level. This study examined the offspring of parents with premature coronary artery disease and hyperapobetalipoproteinemia. A substantial portion, that is in 3, had hyperapobetalipoproteinemia and of these only the minority had clearly elevated plasma triglyceride or LDL cholesterol levels. Thus, hyperapobetalipoproteinemia appears to be present frequently in the offspring of affected families, an observation which may explain, at least in part, the familial aggregation of coronary artery disease.

296 Continuous Positive Airway Pressure by Face Mask in Acute Cardiogenic Pulmonary Edema

JUKKA RÄSÄNEN, JUHANI HEIKKILÄ, JOHN DOWNS, PERTTI NIKKI, IRMA VAISANEN, and ANNE VIITANEN

Continuous positive airway pressure administered by face mask was compared prospectively to ambient airway pressure breathing in 40 patients with respiratory failure from acute cardiogenic pulmonary edema. The use of 10 cm H_2O continuous positive airway pressure improved gas exchange and reduced work of breathing within 10 minutes. Simultaneously, heart rate and systolic blood pressure decreased, indicating relief of the circulatory stress associated with pulmonary edema. No complications occurred with either treatment. The patients treated with an ambient airway pressure appeared to be at greater risk of requiring endotracheal intubation and ventilator treatment than those who received continuous positive airway pressure.

301 Intracoronary Thrombolytic Therapy in Acute Myocardial Infarction: A Prospective, Randomized, Controlled Trial

ALBERT E. RAIZNER, FRANCISCO A. TORTOLEDO, MARIO S. VERANI, RICHARD E. VAN REET, *with* JAMES B. YOUNG, FRANK D. RICKMAN, W. RICHARD CASHION, DAVID A. SAMUELS, CRAIG M. PRATT, MOHAMMED ATTAR, HOWARD S. RUBIN, JOHN M. LEWIS, MILTON S. KLEIN, *and* ROBERT ROBERTS

A prospective, randomized trial was designed to assess the efficacy of intracoronary thrombolytic therapy with streptokinase (STK) in acute myocardial infarction. Sixty-four patients were randomized into a traditional control group, an intracoronary STK group and a nitroglycerin group that was treated identically to the STK group except that the patients did not receive STK. Global ejection fraction (EF) by radionuclide ventriculography measured before therapy and 7 to 10 days later demonstrated wide variability of response among persons in all groups but improved significantly in the STK-recanalized patients. The greatest magnitude of improvement occurred in STK-recanalized patients whose EF was low ($\leq$45) on admission. Regional EF of the infarcting segments improved in the STK group as a whole, and more strikingly, in the STK-recanalized patients.

309 Intravenous Versus Intracoronary Streptokinase in Acute Myocardial Infarction

RUSSELL P. VALENTINE, DOUGLAS E. PITTS, JO ANN BROOKS-BRUNN, JAMES G. WILLIAMS, EUGENE VAN HOVE, and PAUL E. SCHMIDT

Sixty-six patients with acute myocardial infarction treated with intravenous (i.v.) streptokinase (STK) were compared with 98 patients treated with intracoronary (i.c.) STK in a prospective trial of coronary thrombolysis. Lysis occurred in 51% of patients who received i.v. STK and 59% of patients who received i.c. STK. A significant reduction in time from onset of pain to administration of STK occurred. Complications were identical in the 2 groups. Patients in whom reperfusion was achieved had a significantly greater ejection fraction increase than those in whom it was not. It is concluded that the safety and efficacy of i.v. and i.c. STK are equivalent, and that i.v. STK offers significant advantages in shortening time to treatment and in making lytic therapy more widely available.

313 Follow-Up After Coronary Arterial Reperfusion with Intravenous Streptokinase in Relation to Residual Myocardial Infarct Artery Narrowings

ROLF SCHRÖDER, HANS VÖHRINGER, THOMAS LINDERER, GIANCARLO BIAMINO, THOMAS BRÜGGEMANN, and ENZ-RUDIGER V. LEITNER

Quantitative measurements of the diameter stenosis after 24 hours and in the fourth week after successful intravenous thrombolysis in 15 patients revealed a significant decrease from 62 to 55%. Sixty-three patients with a patent infarct-related artery in the fourth week were followed up for a mean of 34 months. Fifty-nine percent of patients have had a stenosis less than 65%, and 41% have had a stenosis greater than 65% in diameter.

Continued on page A24

Eighteen patients underwent repeat study after 26 months (range 18 to 40). It appears that in patients with a residual stenosis less than 65% in the fourth week after successful intravenous streptokinase, reocclusion or reinfarction is a relatively rare event, whereas it is frequent in patients with a more severe residual stenosis. Percutaneous transluminal coronary angioplasty may be advisable in these latter patients.

318 Value of Radionuclide Angiography for Predicting Specific Cardiac Events After Acute Myocardial Infarction

KENNETH G. MORRIS, SEBASTIAN T. PALMERI, ROBERT M. CALIFF, RAY A. McKINNIS, MICHAEL B. HIGGINBOTHAM, R. EDWARD COLEMAN, and FREDERICK R. COBB

The value of rest and exercise radionuclide angiography (RNA) for predicting specific events including death, recurrent infarction, coronary care unit readmission for unstable chest pain and medically refractory angina after acute myocardial infarction (AMI) was studied in 106 consecutive survivors of AMI. RNA measures of left ventricular function, rest and exercise ejection fraction, were predictive of subsequent mortality, whereas the change in ejection fraction from rest to exercise, which reflects residual potentially ischemic myocardium, was predictive of subsequent ischemic events. Significant correlations were found between RNA variables and a variety of clinical descriptors previously reported to have prognostic significance. Rest and exercise RNA after AMI provides significant prognostic information regarding specific events during follow-up independent of that provided by clinical assessment.

325 Prognostic Significance of Precordial ST-Segment Depression During Inferior Acute Myocardial Infarction

MARK A. HLATKY, ROBERT M. CALIFF, KERRY L. LEE, DAVID B. PRYOR, GALEN S. WAGNER, and ROBERT A. ROSATI

The significance of precordial ST-segment depression during inferior acute myocardial infarction (AMI) is controversial. In 162 such patients it was found that those with ST depression in leads V_1 through V_3 developed significantly larger infarcts as assessed by a QRS scoring system. Hospital mortality was 4% (3 of 75 patients) among patients without ST depression, and 13% (11 of 87) in patients with ST depression. The relation between the amount of ST depression and hospital mortality remained significant ($p < 0.003$) after adjusting for other potentially prognostic factors. Among patients discharged from the hospital, the 5-year survival was 92% in those without precordial ST depression and 80% in those with precordial ST depression. Thus, precordial ST-segment depression on the admission electrocardiogram during an inferior acute myocardial infarction indicates a larger infarction, predicts a higher hospital mortality, and suggests a worse long-term prognosis after discharge.

330 Isosorbide Dinitrate Sublingual Therapy for Inferior Myocardial Infarction: Randomized Trial to Assess Infarct Size Limitation

PEDRO PABÓN OSUNA, LUIS M. GARCÍA MORENO, ANTONIO ARRIBAS JIMENEZ, ANGEL SALA, SÁNCHEZ-CASTILLO, CÁNDIDO MARTÍN LUENGO, JOSÉ SÁNCHEZ HERNÁNDEZ, LUIS CASTAÑO BAZO, MANUEL CASCON BUENO, MAXIMILIANO DIEGO DOMINGUEZ, and CLAUDIO LESDESMA GARCÍA

To evaluate whether sublingual isosorbide dinitrate can reduce infarct size, 41 patients with acute myocardial infarction were randomized to control ($n = 20$) and treatment ($n = 21$) groups. Patients in the treatment group received 10 mg of isosorbide dinitrate every 2 hours. Infarct size was estimated by QRS scoring, peak creatine kinase (CK) blood levels and CK curves. There was no significant difference between the groups in maximal or cumulative CK levels or QRS score (16.5% of left ventricle infarcted in the control group and 17% in the treatment group). In both groups the QRS score increased significantly at 13 hours after MI, and the increase was highly significant at 19 to 23 hours. Thus, sublingual isosorbide dinitrate did not reduce infarct size in patients with inferior myocardial infarction.

335 Frequency of Pericardial Effusion as Determined by M-Mode Echocardiography in Acute Myocardial Infarction

KERRY KAPLAN, RICHARD DAVISON, MICHELE PARKER, JEAN PRZYBYLEK, AMY LIGHT, DENNIS BRESNAHAN, HILLEL RIBNER, and JAMES V. TALANO

A pericardial friction rub occurs in 6 to 16% of patients after acute myocardial infarction (AMI), but the incidence of pericardial effusion (PE) is unknown. M-mode echocardiography was done 1, 3 and 5 days after AMI in 43 consecutive patients admitted within 24 hours of an AMI, and PE was detected in 16 (37%). The size of the PE was small in 7, moderate in 6 and large in 3. A pericardial friction rub developed in 8 (19%) of whom only 4 had PE. Pleuritic chest pain diminished by sitting up and relieved by anti-inflammatory agents developed in 12 (28%), of

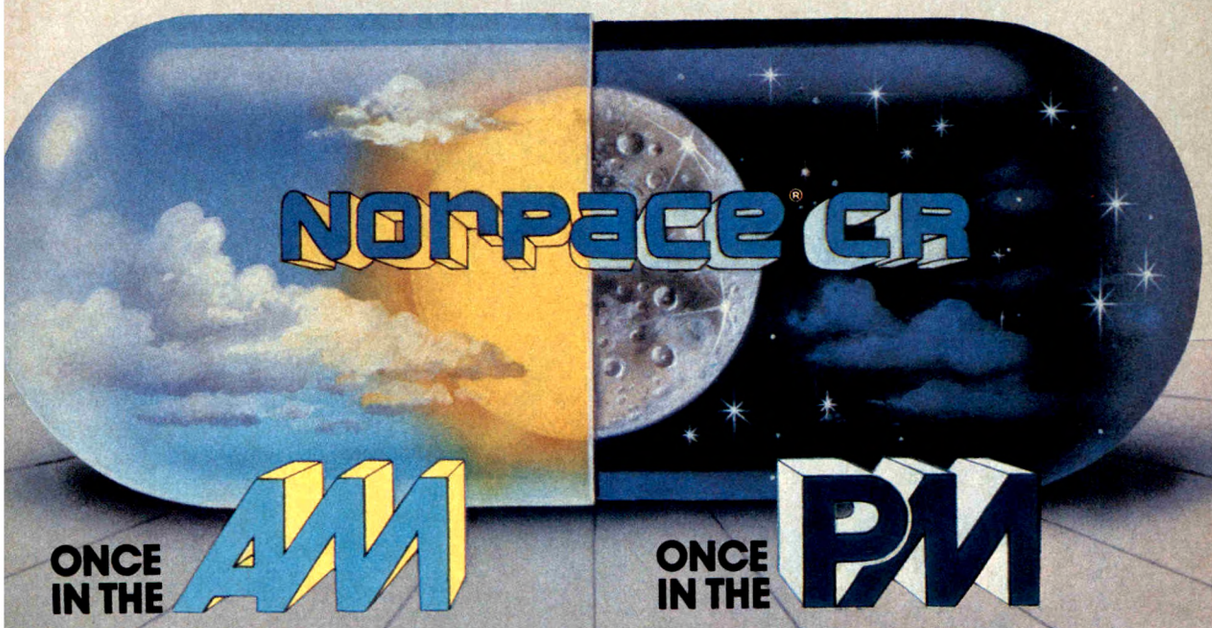
THINK "TWICE"



PREDICTABILITY IN A B.I.D. DOSAGE

Norpace® CR

(disopyramide phosphate)

CONTROLLED-RELEASE 100-mg and 150-mg 12-HOUR CAPSULES

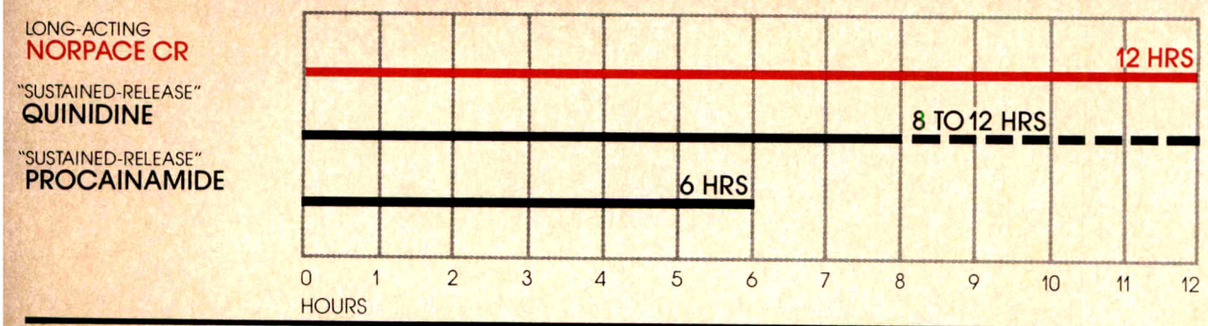
The most commonly seen side effects of disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties.

Please see next page for a brief summary of the complete prescribing information.

SEARLE

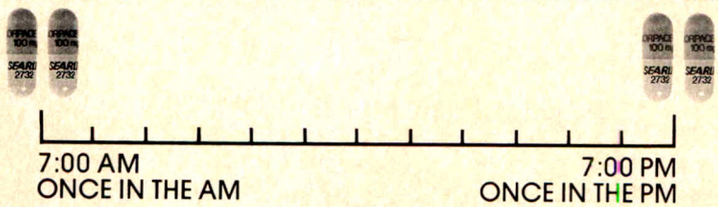
PREDICTABILITY IN A B.I.D. DOSAGE

DURATION OF ANTIARRHYTHMIC ACTION



Norpace® CR
(disopyramide phosphate)

CONTROLLED-RELEASE 100-mg and 150-mg 12-HOUR CAPSULES



Brief Summary

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention especially in males with benign prostatic hypertrophy, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

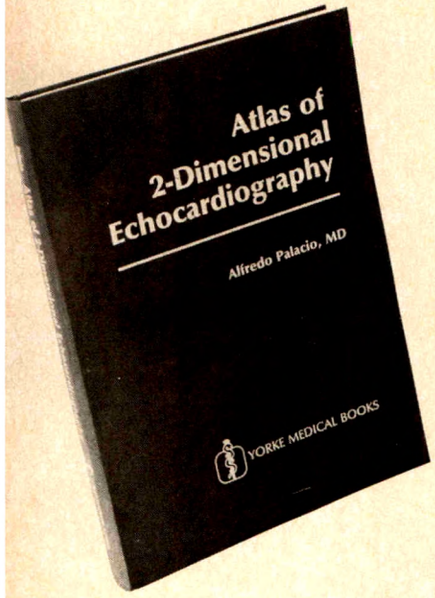
The First Practical Atlas of 2-D Echocardiography Ever Published



-dimensional echocardiography com-lemented by M-mode echocardiography as become one of the most common oninvasive diagnostic tools used by the ardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCAR-DIOGRAPHY, neophyte and expert alike ow have available to them the most truly sable didactic presentation of the subject ver published.

A true atlas, this book provides in a **large 8¼ × 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail ow to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads he reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations n its technical sections will ensure the superior level of performance of echocar-diographic techniques that is a sine qua non for good results.

To order your copy of this impor-tant new book use the order form to the right.

A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts
ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ × 12, March '83, $69.00

Visken® (pindolol)

5-mg and 10-mg Tablets

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken® (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/ kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

	Total (Volunteered and Elicited)		
Body System/ Adverse Reaction	Visken (pindolol) (N = 322) %	Active controls* (N = 188) %	Placebo (N = 78) %

* Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

More than 7 million patient-years of experience

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointenstinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥ 80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. An antihypertensive response usually occurs within the first week of treatment. Maximal response, however, may take as long as or occasionally longer than two weeks. If a satisfactory reduction in blood pressure does not occur within 3-4 weeks, the dose may be adjusted in increments of 10 mg per day at these intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

whom only 5 had PE. In conclusion, PE as detected by M-mode echocardiography is frequently present after AMI; and its presence is not closely associated with the occurrence of a pericardial friction rub or typical pericardial pain.

338 Contractile Properties of the Left Ventricle with an Aneurysm

STEPHEN ARVAN and PEDRO BADILLO

Percent fractional shortening properties of the left ventricle were analyzed by 2-dimensional echocardiography in 25 subjects who sustained their first anterior wall acute myocardial infarction. In 8 of the 25 subjects a left ventricular (LV) aneurysm subsequently developed. The percent fractional shortening of the basal and mid-LV segments was significantly better in group I subjects than in group II subjects. Infarct size as determined by peak creatinine kinase isoenzyme levels was large in both groups and were not significantly different from each other. Severe asynergy of the infarcted myocardium was more common in the group of patients with LV aneurysm. These results indicate that LV aneurysm formation depends upon a critical imbalance of myocardial forces where strong LV segmental contractility causes bulging of weakened ones.

342 Assessment of Hemodynamic Significance of Isolated Stenoses of the Left Anterior Descending Coronary Artery Using Thallium-201 Myocardial Scintigraphy

VICTOR KALFF, MICHAEL J. KELLY, ALAN SOWARD, RICHARD W. HARPER, PHILIP J. CURRIE, YEAN L. LIM, and AUBREY PITT

In 22 patients with isolated single-vessel left anterior descending coronary artery stenoses who were undergoing percutaneous transluminal coronary angioplasty, the results of exercise thallium-201 myocardial perfusion scintigraphy were independently predictive of the mean transstenotic pressure gradient ($p < 0.003$) after taking into account the assessment provided by coronary angiography. It is suggested that this additional information may be of most value when a coronary stenosis is less than 90% luminal diameter narrowing and its clinical significance is uncertain.

347 Clinical, Angiographic, Hemodynamic, Perfusional and Functional Changes after One-Vessel Left Anterior Descending Coronary Angioplasty

ROBERT D. OKADA, YEAN L. LIM, CHARLES A. BOUCHER, GERALD M. POHOST, DAVID A. CHESLER, and PETER C. BLOCK

Percutaneous transluminal coronary angioplasty (PTCA) was successfully performed in 20 patients with 1-vessel left anterior descending coronary artery disease. Peak workload, heart rate and systolic blood pressure all increased significantly after PTCA. Of 12 patients with an abnormal exercise electrocardiogram before PTCA, 8 had normal electrocardiograms after the procedure. Significant improvement in thallium activity was present in the anterior and septal segments of the left ventricle 1 week after PTCA. In addition, there was a significant reduction in the amount of thallium redistribution between initial and delayed images and improvements in the clearance rates from these same regions. Exercise ejection fraction response and septal wall motion also improved after PTCA. Thus, improvement in clinical, angiographic and hemodynamic factors, as well as in global and regional myocardial perfusion and function occur after PTCA.

357 Early Detection of Restenosis After Successful Percutaneous Transluminal Coronary Angioplasty by Exercise-Redistribution Thallium Scintigraphy

WILLIAM WIJNS, PATRICK W. SERRUYS, JOHAN H.C. REIBER, PIM J. de FEYTER, MARCEL van den BRAND, MAARTEN L. SIMOONS, and PAUL G. HUGENHOLTZ, *with the statistical assistance of* JAN G.P. TIJSSEN

Exercise-induced ischemia as evidenced from early and late (4 hours) postexercise thallium scintigraphy was observed in 35 of 89 asymptomatic patients 4 weeks after a primary successful percutaneous transluminal coronary angioplasty. All patients had a clinical follow-up and a control coronary angiogram a median of 6 months later. The findings of an initially abnormal scintigram was associated with a high incidence of restenosis at late angiography (positive predictive value 74%). This suggests that restenosis had already occurred to some extent at 4 weeks in most patients in whom it was going to occur.

362 **Comparison of Preoperative, Operative and Postoperative Variables in Asymptomatic or Minimally Symptomatic Patients to Severely Symptomatic Patients Three Years After Coronary Artery Bypass Grafting: Analysis of 423 Patients**

PIM J. de FEYTER, PATRICK W. SERRUYS, RONALD W. BROWER, MARCEL van den BRAND, HARALD J. ten KATEN, PAUL G. HUGENHOLTZ, and EGBERT BOS

During a 3-year follow-up of 423 patients who underwent coronary artery bypass graft surgery, the incidence of patients in New York Heart Association class III to IV was 19%. This adverse outcome could not be predicted from 80 clinical, angiographic and perioperative variables, but was associated with a high attrition rate of the grafts. The reoperability rate was 54%. Of the patients in whom reoperation could not be performed, half of them improved to class I to II with intensive medical treatment. The reoperable patients were initially offered an intense medical treatment, which resulted in an improvement to class I to II in one-third of the patients. The nonresponders underwent reoperation after which the majority improved to class I to II.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

367 **Usefulness of Electrophysiologic Testing in Evaluation of Amiodarone Therapy for Sustained Ventricular Tachyarrhythmias Associated with Coronary Heart Disease**

LEONARD N. HOROWITZ, ALLAN M. GREENSPAN, SCOTT R. SPIELMAN, CHARLES R. WEBB, JOEL MORGANROTH, HESCHI ROTMENSCH, NEIL M. SOKOLOFF, ALAN P. RAE, BERNARD L. SEGAL, and HAROLD R. KAY

The clinical value of electrophysiologic testing of amiodarone was assessed in a prospective study of 100 consecutive patients with sustained ventricular tachyarrhythmias treated with amiodarone. In 20 patients in whom ventricular tachycardia could no longer be initiated after amiodarone therapy there were no recurrences of arrhythmia. In patients in whom ventricular tachycardia remained inducible there were recurrences in 38 of 80 patients (48%). The severity of the recurrence was predicted by electrophysiologic testing. This study suggests that electrophysiologic testing is useful in the clinical management of patients with ventricular tachyarrhythmias treated with amiodarone.

372 **Cardiac Arrest and Sudden Death in Patients Treated with Amiodarone for Sustained Ventricular Tachycardia or Ventricular Fibrillation: Risk Stratification Based on Clinical Variables**

LORENZO A. DICARLO Jr., FRED MORADY, MARY JANE SAUVE, PATRICIA MALONE, JESSE C. DAVIS, THOMAS EVANS-BELL, STUART A. WINSTON, and MELVIN M. SCHEINMAN

Multivariate analysis of 11 clinical variables was performed in 104 patients with sustained, symptomatic ventricular tachycardia (VT) or ventricular fibrillation treated with amiodarone. Twenty-five patients (24%) had cardiac arrest or sudden death after 7.3 ± 6.2 (mean ± standard deviation) months of therapy. Multivariate analysis identified an ejection fraction less than 0.40, syncope or cardiac arrest before amiodarone therapy, and VT (3 or more consecutive ventricular premature depolarizations) during predischarge ambulatory electrocardiographic monitoring as variables associated with a high risk of subsequent cardiac arrest or sudden death ($p < 0.03$). Patients who had these 3 clinical variables had a much higher incidence of cardiac arrest or sudden death at 6 months (62%) and 12 months (76%) than did patients with an ejection fraction of 0.40 or greater, without syncope or cardiac arrest before amiodarone therapy, and without VT during predischarge ambulatory electrocardiographic monitoring (2% and 5%, respectively, $p < 0.02$). Risk stratification using clinical variables can predict which patients are at high risk of cardiac arrest or sudden death during amiodarone therapy.

375 **Results of Late Programmed Electrical Stimulation and Long-Term Electrophysiologic Effects of Amiodarone Therapy in Patients with Refractory Ventricular Tachycardia**

ENRICO P. VELTRI, PHILIP R. REID, EDWARD V. PLATIA, and LAWRENCE S.C. GRIFFITH

Thirteen patients with recurrent sustained ventricular tachycardia (VT) were treated with amiodarone. At control electrophysiologic study, programmed electrical stimulation (PES) induced VT in all patients: sustained VT in 11 and nonsustained VT in 2 (9 beats and 31 beats). PES at 6 ± 1.6 months (mean ± standard error) of amiodarone therapy revealed inducible VT in 12 of 13 patients: sustained VT in 11 and nonsustained VT in 1 patient (32 beats); only 1 patient with inducible VT at control study had VT suppressed at late study. At 24 ± 2 months of follow-up, 8 patients (62%) (all with inducible VT at late PES) were free of clinical arrhythmic events (syncope, sudden death), compared with 5 patients (38%) (4 with inducible VT at late PES) with events. There were no significant differences in VT cycle length, VT cycle length change, ease of inducibility or hemodynamic response to induced VT at late PES in patients with and without arrhythmic events. Thus, in patients receiving long-term ami-

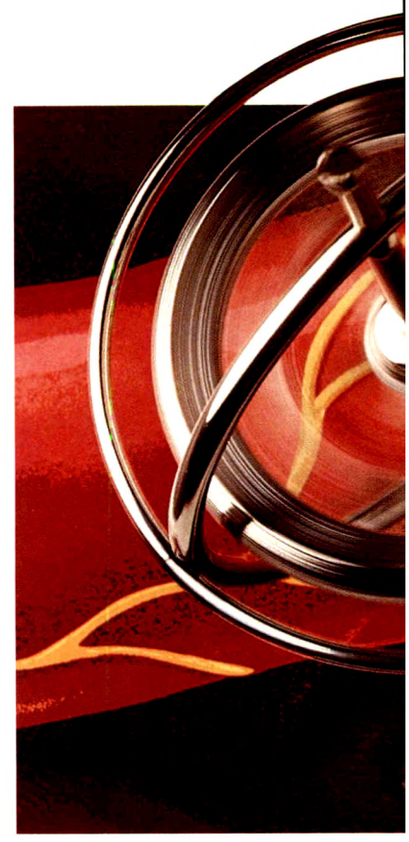
BALANCED CALCIUM CHANNEL BLOCKADE

CARDIZEM®
(diltiazem HCl)

A balance of poten with a low incid

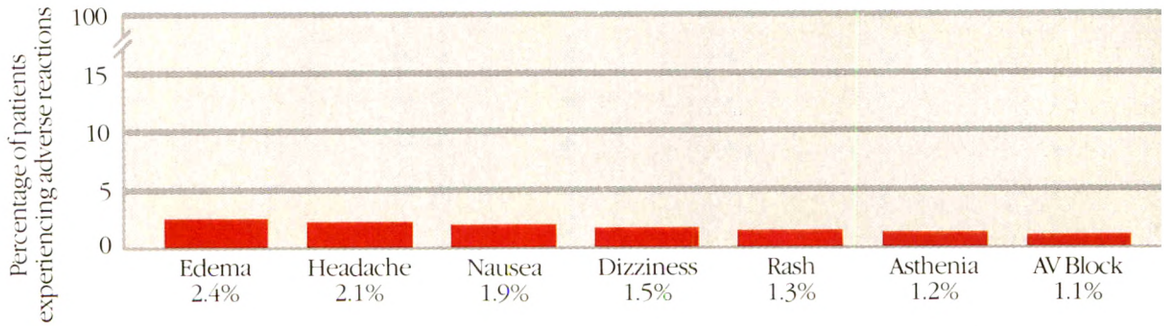
In the treatment of angina pectoris, calcium channel blockers have been found to be potent coronary vasodilators. And, due to its balanced hemodynamic profile, CARDIZEM® (diltiazem HCl) produces a low incidence of side effects, thus contributing to the patient's sense of well-being.

"The lack of significant adverse effects with diltiazem appears to correlate with the high rate of acceptance of the drug by patients and the drug's safety in both short- and long-term use."[1]



Low incidence of side effects

The adverse reactions reported most frequently with Cardizem have been:

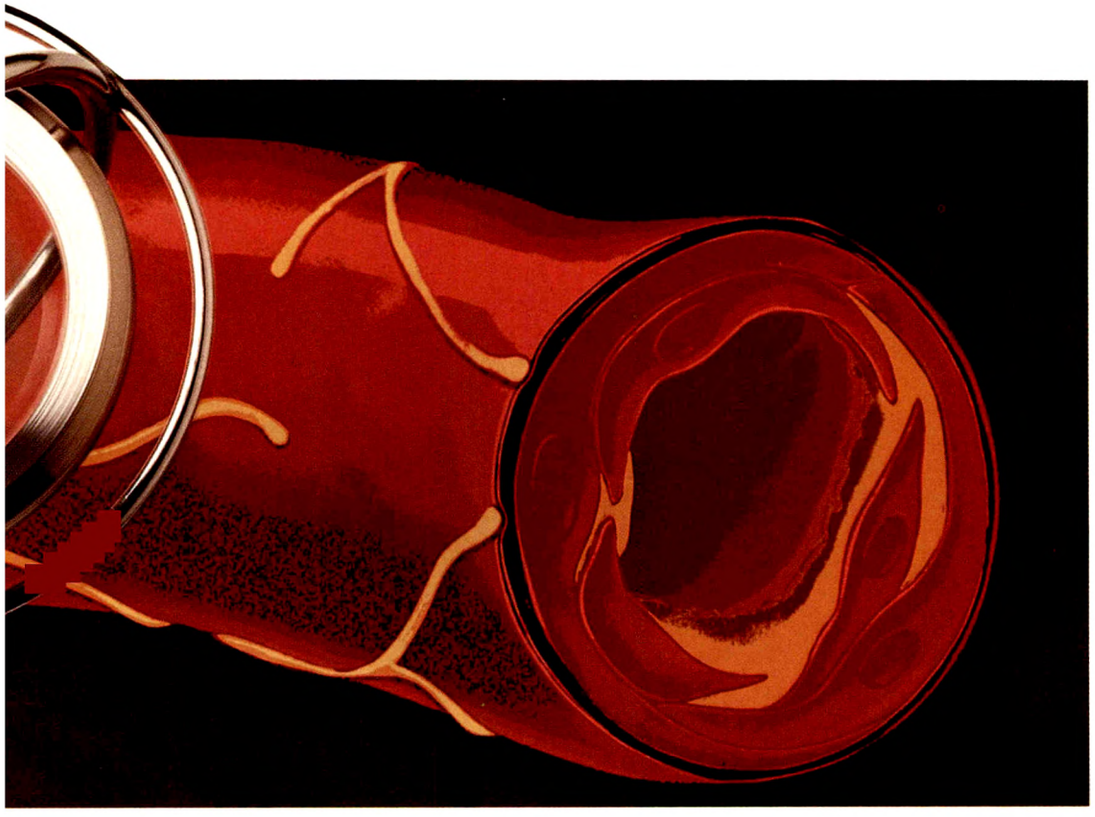


In many cases, the relationship to Cardizem has not been established.

In placebo-controlled US trials, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therap

For other adverse reactions infrequently report (<1.0%), see full prescribing information on last pag of this ad.

ɔı onary vasodilation
cɛ of side effects



Increases exercise tolerance*

CARDIZEM® (diltiazem
ɔl) allows patients to signifi-
ntly prolong exercise tolerance
en in demanding Bruce proto-
l exercise tests.[2] In time to
ıset of pain, control patients
eraged 8.0 minutes; Cardizem
ıtients averaged 9.8 minutes.

Reduces angina attack frequency*

42% to 46% decrease in effort angina attacks reported in multicenter study.[3]

CARDIZEM®
(diltiazem HCl)

The balanced calcium channel blocker

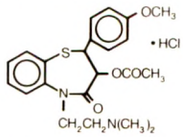
lizem is indicated in the treatment of chronic stable
ına (classic effort-associated angina) and angina due to
ɔnary artery spasm.

PROFESSIONAL USE INFORMATION

cardizem®
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy) -5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+)-cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem hydrochloride for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate-blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studi which can be at least reasonably associated with the pharmacology calcium influx inhibition. In many cases, the relationship to CARDIZE has not been established. The most common occurrences, as well their frequency of presentation, are: edema (2.4%), headache (2.1% nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), block (1.1%). In addition, the following events were reported infrequen (less than 1%) with the order of presentation corresponding to t relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradyca dia, palpitations, congestive heart failu syncope.
Nervous System:	Paresthesia, nervousness, somnolenc tremor, insomnia, hallucinations, and amnes
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomitir mild elevations of alkaline phosphatase, SG SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivi
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vas spastic angina developed periods of transient asymptomatic asyst approximately five hours after receiving a single 60-mg dose CARDIZEM.

The following postmarketing events have been reported inf quently in patients receiving CARDIZEM: erythema multiforme; le kopenia; and extreme elevations of alkaline phosphatase, SG SGPT, LDH, and CPK. However, a definitive cause and effect betwe these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Sin oral doses of 300 mg of CARDIZEM have been well tolerated healthy volunteers. In the event of overdosage or exaggerated sponse, appropriate supportive measures should be employed addition to gastric lavage. The following measures may be considere

Bradycardia	Administer atropine (0.60 to 1.0 mg). If the is no response to vagal blockade, administ isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed hig degree AV block should be treated with c diac pacing.
Cardiac Failure	Administer inotropic agents (isoproteren dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterer bitartrate).

Actual treatment and dosage should depend on the severity of t clinical situation and the judgment and experience of the treati physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg a from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in the species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs considered to be in excess of 50 mg/kg, while lethality was seen monkeys at 360 mg/kg. The toxic dose in man is not known, but blo levels in excess of 800 ng/ml have not been associated with toxici

DOSAGE AND ADMINSTRATION

Exertional Angina Pectoris Due to Atherosclerotic Cor nary Artery Disease or Angina Pectoris at Rest Due to Cor nary Artery Spasm. Dosage must be adjusted to each patier needs. Starting with 30 mg four times daily, before meals and bedtime, dosage should be increased gradually (given in divid doses three or four times daily) at one- to two-day intervals ur optimum response is obtained. Although individual patients m respond to any dosage level, the average optimum dosage ran appears to be 180 to 240 mg/day. There are no available d concerning dosage requirements in patients with impaired renal hepatic function. If the drug must be used in such patients, titrati should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acu anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safe coadministered with short- and long-acting nitrates, but the have been no controlled studies to evaluate the antiangir effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

Cardizem 30-mg tablets are supplied in bottles of 100 (NI 0088-1771-47) and in Unit Dose Identification Paks of 100 (NI 0088-1771-49). Each green tablet is engraved with MARION on o side and 1771 engraved on the other. CARDIZEM 60-mg scor tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in U Dose Identification Paks of 100 (NDC 0088-1772-49). Each yell tablet is engraved with MARION on one side and 1772 on the othe

odarone treatment, late PES does not predict clinical efficacy, the frequency of conversion from inducible VT to noninducible is low, and despite ventricular electrical instability as judged by late PES testing, amiodarone is clinically effective in high-risk patients.

380 Comparison in the Same Patient of Two Programmed Ventricular Stimulation Protocols to Induce Ventricular Tachycardia

PEDRO BRUGADA and HEIN J.J. WELLENS

Twenty-four consecutive patients with ventricular tachycardia (VT) (22 patients) or fibrillation (2 patients) were prospectively studied to compare results of 2 different programmed ventricular stimulation protocols to initiate VT. Both protocol 1 and protocol 2 started by pacing at the right ventricular (RV) apex at 100 beats/min using twice threshold current strength and up to 2 ventricular premature complexes (VPC). This initial step had a sensitivity of 25%. In protocol 1 the pacing site was, thereafter, changed to the RV outflow tract and finally the current strength was increased to 20 mA. In protocol 2 neither current strength nor pacing site were varied, but the pacing rate was increased to 120 and 140 beats/min. Thereafter the number of VPCs was increased to 3 during sinus rhythm and ventricular pacing. Protocol 1 had a sensitivity of 54% and protocol 2 a sensitivity of 83% ($p < 0.05$). Sensitivity of protocol 1 and protocol 2 in patients with VT and old myocardial infarction was 66 and 93%, respectively. When results after administration of isoproterenol were added to results of protocol 2, the sensitivity was 95% for the whole patient population, and 100% for patients with healed myocardial infarction. These observations have important implications for the design of the most successful order of programmed ventricular stimulation. Once stimulation at the RV apex using a current strength of twice threshold, a pacing rate of 100 beats/min and a maximum of 2 VPCs has failed to initiate VT, an increase in the pacing rate to 120 and 140 beats/min, and number of VPCs to 3 during sinus rhythm and ventricular pacing is a more effective means of initiating VT than changing pacing site or increasing current strength to 20 mA.

384 Late Potentials in Normal Subjects and in Patients with Ventricular Tachycardia Unrelated to Myocardial Infarction

HUMBERTO COTO, CLAUDIO MALDONADO, PRASAD PALAKURTHY, and NANCY C. FLOWERS

In this study, 50 normal athletes or athletically active subjects were evaluated for late potentials. Three normal men had late potentials indistinguishable by present analytic techniques from those encountered in postinfarction patients in whom ventricular tachycardia developed. The other 47 were recognized as normal by the absence of such markers. Of 24 patients referred for disturbances of rhythm or conduction, 11 had ventricular tachycardia and were considered in the study. Only 2 had had a myocardial infarction in the remote past. Although group differences could be demonstrated, late potentials were not found to be an impressive marker of the patient with ventricular tachycardia. Thus, the absence of late potentials was an effective marker of normal subjects, but the presence of late potentials was not an effective marker in identifying non-infarct-related, nonsustained ventricular tachycardia patients.

391 Ventricular Arrhythmia Induced by Programmed Ventricular Stimulation After Acute Myocardial Infarction

PIETRO SANTARELLI, FULVIO BELLOCCI, FRANCESCO LOPERFIDO, MARIO MAZZARI, ROCCO MONGIARDO, ANNIBALE S. MONTENERO, UGO MANZOLI, and PABLO DENES

The prevalence, characteristics and clinical features of ventricular electrical instability assessed by programmed ventricular stimulation were studied in 50 hemodynamically stable patients 17 to 40 days after myocardial infarction. Ventricular electrical instability was defined as induction of 10 or more consecutive intraventricular reentrant beats. Of 50 patients, 23 (46%) had ventricular electrical instability (in 10 of whom sustained ventricular tachycardia was induced). During a mean follow up of 11.2 months no sudden death occurred. It is concluded that there is a high prevalence of ventricular electrical instability after acute myocardial infarction, not predicted by noninvasive tests.

395 Bretylium: Relations Between Plasma Concentrations and Pharmacologic Actions in High-Frequency Ventricular Arrhythmias

HENRY J. DUFF, DAN M. RODEN, AVRAHAM YACOBI, DAVID ROBERTSON, THEODORE WANG, REBECCA J. MAFFUCCI, JOHN A. OATES, and RAYMOND L. WOOSLEY

The relation between concentration and pharmacologic response to bretylium was assessed in 6 patients with high-frequency ventricular arrhythmia. Patients received bretylium at 2.5 mg/kg, 5 mg/kg, 10 mg/kg and placebo in a randomized sequence. Adrenergic neuronal blockade developed early and at a time when relatively small amounts of bretylium had been administered. The frequency of an early sympathomimetic response increased

SLOW-K® potassium chloride slow-release tablets

Brief Summary of Prescribing Information

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.

The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years), cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS

The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION

The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

with dosage and its occurrence was temporally related to the onset of adrenergic neuronal blockade, and increase in plasma norepinephrine. Increase in ventricular arrhythmia frequency occurred in relation to the sympathomimetic phase.

402 Continuous Electrical Activity During Sustained Monomorphic Ventricular Tachycardia: Observations on Its Dynamic Behavior During the Arrhythmia

PEDRO BRUGADA, HOSHIAR ABDOLLAH, and HEIN J.J. WELLENS

Catheter mapping during monomorphic ventricular tachycardia (VT) revealed continuous electrical activity in 20 of 56 consecutive patients (in 15 of 42 with old myocardial infarction, 5 of 6 with right ventricular dysplasia and 0 of 8 with idiopathic VT). In 17 of 20 patients showing continuous electrical activity during VT at least 1 of the following observations was made: (1) Spontaneous disappearance of continuous electrical activity without changes in rate, morphology or axis of VT. (2) Pacing-induced transient termination of continuous electrical activity without termination of VT. (3) Spontaneous disappearance of continuous electrical activity during VT as a rate-dependent phenomenon. (4) Wenckebach-like conduction to other areas resulting in transient and periodic continuous electrical activity. (5) Dependence of continuous electrical activity from ventricular activation pattern during VT. (6) Pacing-induced change from noncontinuous electrogram into continuous electrical activity without prevention of termination of VT. (7) Termination of continuous electrical activity following antiarrhythmic drugs without termination of VT. These observations demonstrate that several electrophysiologic phenomena can simulate continuous electrical activity during monomorphic VT. Transient continuous electrical activity is a frequent phenomenon representing electrical activity from abnormal areas not necessarily required to perpetuate VT.

412 Arrhythmias Induced During Termination of Supraventricular Tachycardia

BERND WALDECKER, PEDRO BRUGADA, KAREL den DULK, MANFRED ZEHENDER, and HEIN J.J. WELLENS

To evaluate arrhythmias induced by attempted termination of supraventricular tachycardia (SVT), 453 attempts to interrupt SVT by pacing in 111 patients were analyzed. Seventy-six patients had SVT using an accessory atrioventricular bypass and 35 patients had intranodal SVT. The extrastimulus technique and overdrive pacing were performed from the atrium and ventricle. Atrial flutter or fibrillation, other SVT, nonsustained ventricular tachycardia, as well as inability to terminate SVT without initiating another arrhythmia, were observed. Pacing-induced arrhythmias during attempted termination of SVT were evaluated qualitatively and quantitatively. Assessment of the safety of antitachycardia pacing by careful investigation during programmed electrical stimulation is mandatory in every patient before considering use of an antitachycardia pacemaker for treatment of SVT.

SYSTEMIC HYPERTENSION

418 Maximal Hand Blood Flow in Hypertensive and Normal Subjects

DAVID HORWITZ and DALI J. PATEL

Hypertensive and normal subjects were studied under conditions of maximal vasodilation wherein flow at a given driving pressure was considered to give an index of structural changes in resistance vessels. Flow was measured by venous occlusion plethysmography after 10 minutes of ischemia, and arterial pressure was measured by the arm cuff method. Flow at a transmural pressure of 85 mm Hg was calculated for each subject. Mean flow for normal subjects was 41 ml/100 ml/min and differed significantly from that of the patients with sustained hypertension (30 ml/100 ml/min).

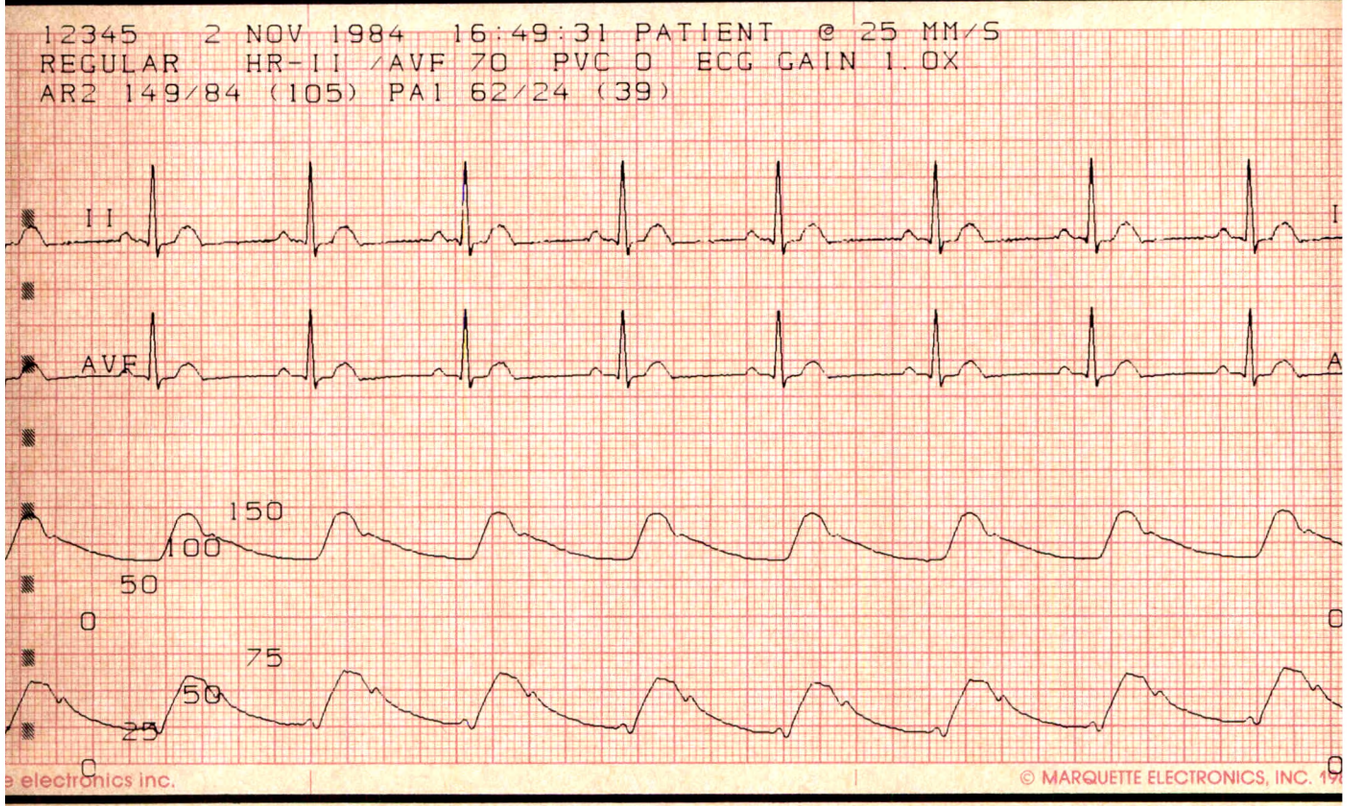
CONGESTIVE HEART FAILURE

423 Vascular Hemodynamic Impedance in Congestive Heart Failure

STANLEY M. FINKELSTEIN, JAY N. COHN, V. ROSS COLLINS, PETER F. CARLYLE, and WENDA J. SHELLEY

Differences in peripheral vascular state between patients with congestive heart failure (CHF) and the healthy population were determined by pulse-contour analysis. Vascular hemodynamic impedance parameters (compliance and resistance) were determined from brachial artery pressure waveforms recorded from a group of 14 patients and 7 healthy control subjects using computer analysis of the diastolic waveforms and a modified Windkessel model of the circulation. Cardiac output, heart sounds and electrocardiograms were also monitored. Mean arterial pressure was similar in the 2 groups, but cardiac output was significantly lower and heart rate significantly higher in the CHF group than in the healthy control subjects. Systemic vascular resistance was slightly

Documentation



2 ECG traces; 2 pressure traces; real time data

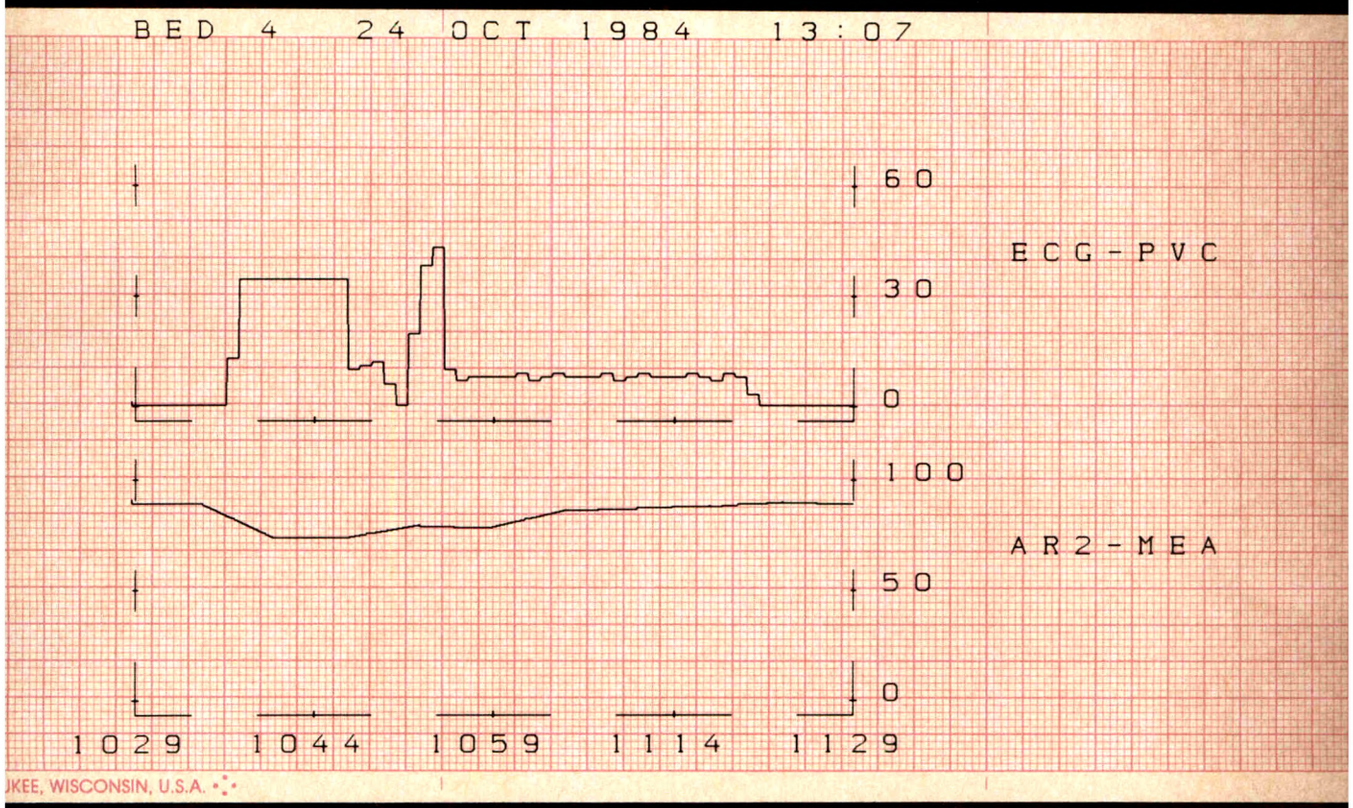
Marquette Electronics' Direct Digital Writer redefines patient monitoring documentation

A considerable amount of vital information can be displayed on your monitor screen . . . trends, ECG histories, stored data, simultaneous waveforms from many parameters . . . but, until now, getting fast, accurate documentation of that information has been impossible.

The Direct Digital Writer (DDW) from Marquette Electronics has rewritten the rules that used to limit documentation. Now, any information you can display on your monitor screen can be printed in hardcopy using just one device, not two as with most other systems. With the DDW, you can simultaneously plot four physiological waveforms in real time, quickly and accurately print stored data, and print any combination of stored and real time data you need.

The DDW automatically calibrates and annotates pressure waveforms as it prints them; this means

ewritten



PVC and mean arterial pressure; trend of stored data

you have a precise reference at all times. And because the DDW has only one moving part—the paper drive—it's more accurate and reliable. Resolution and linearity far exceed those of conventional units because patient information is inscribed directly from digital waveforms (at an ECG resolution of 12.5 microvolts)... there's no distortion, no response problems, no overshoot or damping problems.

Application flexibility is another feature inherent in DDW... it can be used as a stand-alone unit with any Series 7000 monitoring system, it can be used as a mobile printer, or it can be integrated into the Series 7500 central station system.

Call your Marquette Electronics representative. Find out how we've rewritten the rules of critical care documentation.

ALDOMET® (Methyldopa | MSD) tablets do not

TABLETS: 500 mg, 250 mg, and 125 mg

While the presence of sodium metabisulfite is probably important in a limited number of patients, it could be a factor in deciding whether to allow substitution for a prescription of ALDOMET®.

Although Tablets ALDOMET® do not contain any sulfite preservatives, as the Prescribing Information indicates, Oral Suspension ALDOMET® (Methyldopa, MSD) and Injection ALDOMET® Ester HCl (Methyldopate HCl, MSD) do contain sodium bisulfite as a preservative.

The use of any of these products is contraindicated in hypersensitive patients, in active hepatic disease, or if previous methyldopa therapy has been associated with liver disorders.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

A45

ALDOMET® (METHYLDOPA|MSD)

ALDOMET® Ester HCl (METHYLDOPATE HCl|MSD)

Tablets, containing 125, 250, or 500 mg methyldopa. Oral Suspension, containing 250 mg methyldopa per 5 ml and alcohol 1% with benzoic acid 0.1% and sodium bisulfite 0.2% added as preservatives. Injection for intravenous use, containing per 5 ml: methyldopate hydrochloride 250.0 mg; inactive ingredients—citric acid anhydrous 25.0 mg, disodium edetate 2.5 mg, monothioglycerol 10.0 mg, sodium hydroxide to adjust pH, and methylparaben 7.5 mg, propylparaben 1.0 mg, and sodium bisulfite 16.0 mg added as preservatives.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions. With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood. At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients. Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. A paradoxical pressor response has been reported with intravenous use. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Nervous System/Psychiatric:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, prolonged carotid sinus hypersensitivity, aggravation of angina pectoris. Paradoxical pressor response with intravenous use. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear) *Digestive:* Nausea, vomiting, distention, constipation, flatus, diarrhea, colitis, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Bone marrow depression, leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis, pericarditis. *Skin:* Rash as in eczema or lichenoid eruption; toxic epidermal necrolysis. *Respiratory:* Nasal stuffiness. *Metabolic:* Rise in BUN. *Urogenital:* Breast enlargement, gynecomastia, lactation, amenorrhea, impotence, decreased libido. *Endocrine:* Hyperprolactinemia. *Musculoskeletal:* Mild arthralgia, with or without joint swelling; myalgia.

Note: Initial adult oral dosage should be limited to 500 mg daily in divided doses when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

MERCK SHARP & DOHME

CARDIOLOGIST: Ohio, BC/BE, with training in invasive and noninvasive procedures, M.D. degree must be from a U.S. medical school. Attractive salary. Please send curriculum vitae and references to: P.O. Box 290, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

HOUSTON—POSITION AVAILABLE FOR BOARD CERTIFIED OR ELIGIBLE INVASIVE CARDIOLOGIST. Accredited 68-physician internal medicine group. For further information, send Curriculum Vitae to Administrator, Diagnostic Clinic of Houston, 6448 Fannin, Houston, Texas 77030.

NON-INVASIVE CARDIOLOGIST—To join progressive Midwestern four-man cardiology group established in 1973. Individual must be Board-certified or Board-eligible in Cardiology. Proficiency in non-invasive procedures is necessary. Competitive salary. Immediate opening. Interested individuals should send CV to Box 375, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Two man group, interested in invasive and non-invasive Cardiologist to locate in the central New Jersey area thirty minutes from New York City. If interested please reply to P.O. Box 2407, Edison, N,J, 08818.

CARDIOLOGIST, BC/BE wanted to join two cardiologists in the New York Metropolitan area invasive/non-invasive office and multi-hospital practice, with open heart program. Reply with CV to Box 370, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

CARDIOLOGIST

BC/BE, non-invasive or invasive, to join large cardiology group. Midwest metropolitan setting. Send CV to Box 365, American Journal of Cardiology, 875 Third Avenue, New York, New York 10022.

higher in the CHF group, but there was considerable overlap between the 2 groups. Distal vascular compliance from pulse-contour analysis was significantly lower in the CHF group, and there was only minimal overlap between the groups. The data therefore suggest that distal compliance is a more sensitive and specific index than systemic vascular resistance to the vascular change in heart failure.

VALVULAR HEART DISEASE

428 Effects of Upright and Supine Position on Cardiac Resting and Exercise Response in Aortic Regurgitation

WEI FENG SHEN, GARY S. ROUBIN, PETER J. FLETCHER, CHRISTOPHER Y-P. CHOONG, BRIAN F. HUTTON, PHILLIP J. HARRIS, and DAVID T. KELLY

Upright and supine radionuclide ventriculography was performed in 15 patients with moderate to severe aortic regurgitation (AR) and 10 control subjects at rest and during exercise. In patients with AR, heart rate was higher during upright exercise, but blood pressure and left ventricular (LV) output were similar during both forms of exercise. LV stroke volume and end-diastolic volume were not altered during supine exercise. LV end-systolic volume and ejection fraction decreased during supine exercise, but both were unchanged during upright exercise. Of 15 patients, 5 in the upright position and 12 in the supine position had an abnormal LV ejection fraction response to exercise ($p < 0.01$). Right ventricular ejection fraction and regurgitant index were similar during both forms of exercise. Thus, LV response to exercise varies with posture in patients with moderate to severe AR.

431 Electrocardiographic Observations in Clinically Isolated, Pure, Chronic, Severe Aortic Regurgitation: Analysis of 30 Necropsy Patients Aged 19 to 65 Years

WILLIAM C. ROBERTS and PAUL J. DAY

Certain electrocardiographic findings are described in 30 necropsy patients with clinically isolated, pure, chronic, severe aortic regurgitation. Their ages ranged from 19 to 65 years (mean 45). The hearts of the 22 men weighed 430 to 1,100 g (mean 717) and of the 8 women 375 to 950 g (mean 638). Four had grossly visible left ventricular (LV) scars. The total 12-lead QRS amplitude in the 30 patients ranged from 109 to 428 mm (mean 272) (19 mm = 1 mV) and in 27 patients (90%) it was >175 mm. The mean QRS amplitude for each of the 12 leads averaged 23 mm. The highest mean QRS voltage occurred in leads V_2 and V_3 (each 38 mm), and the lowest in lead aVR (11 mm). The mean QRS voltage in lead V_5 was higher than that in V_6 (33 vs 28 mm) and in 22 patients (73%) the QRS voltage in V_5 was higher than in V_6. The sum of the S wave in V_1 plus the larger of the R wave in V_5 or V_6 (Sokolow-Lyon index) averaged 51 mm and in 22 patients (73%) it was >35 mm. The Romhilt-Estes voltage criteria for LV hypertrophy was fulfilled even less frequently.

439 Myxoid Degeneration of the Aortic Valve and Isolated Severe Aortic Regurgitation

WARREN M. ALLEN, JACK M. MATLOFF, and MICHAEL C. FISHBEIN

A clinicopathologic study to determine the cause of valve failure was undertaken on 55 patients undergoing valve replacement for pure AR. The clinical histories established a cause in 34 cases: rheumatic in 11, endocarditis in 13, congenital in 4, associated with aortic aneurysms in 4 and Marfan syndrome in 2. In the remaining 21 valves, 13 showed the pathologic finding of myxoid degeneration, defined as significant disruption of the valve fibrosa and its replacement by acid mucopolysaccharides and cystic change. The clinical features of the patients with myxoid degeneration of uncertain cause were as follows: male (85%), elderly (average age 63 years), with a long-standing history of hypertension (77%) and coronary artery disease (46%). Our findings indicate that myxoid degeneration of the aortic valve is a common pathologic endpoint (36% of all valves examined) and in a certain segment of patients may be associated with long-standing hypertension.

445 Value of Multiple Echocardiographic Views in the Evaluation of Aortic Stenosis in Adults by Continuous-Wave Doppler

GEORGE A. WILLIAMS, ARTHUR J. LABOVITZ, JEANNE G. NELSON, and HAROLD L. KENNEDY

Fifty-two patients referred for evaluation of aortic stenosis were examined with Doppler echocardiography to assess the effect of sampling the aortic valve gradient at different sites. Gradients from 0 to 136 mm Hg were adequately recorded from 51 of 52 patients. Maximal calculated gradients from each area were compared in all patients. Comparison of Doppler calculated peak gradient with cardiac catheterization was performed in 23 patients. Apical and right parasternal velocities were not significantly different and could be recorded in 90% of patients. Velocities from the suprasternal window were significantly lower and underestimation tended to in-

Clinical Clues to MIXED ANGINA *No. 1*

Thirty seconds ago he was reading

He wasn't exercising; his myocardial oxygen demand didn't increase. Yet now he's having an angina attack.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at rest, or even during sleep
- at varying levels of exercise
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin!

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

Thirty seconds ago he was reading.

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level a a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and th patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

Reference:

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congesti heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricul dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline pho phatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA (nifedipine) therapy is uncerta in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical sym toms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have be reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregati and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has be demonstrated.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 p tients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocki agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination m increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controll studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal voluntee The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with cor nary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which goxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, a discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin a ticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80 and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently rece ing cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two yea and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a do approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, m and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used duri pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral eden nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5 palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cram nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cram flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balan dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, p pura, allergic hepatitis, gingival hyperplasia, and erythromelalgia. Very rarely, introduction of PROCARDIA therapy w associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocard infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular rhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CA SULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (N 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperat 59° to 77°F (15° to 25°C) in the manufacturer's original container.

crease with the age of the patient. Correlation of the maximal gradient from any window with cardiac catheterization was r = 0.861, and all patients with a gradient >50 mm Hg were accurately identified. Doppler echocardiography from multiple windows is a useful adjunct in the noninvasive evaluation of aortic stenosis.

450 Coronary Artery Luminal Diameter in Aortic Stenosis

SULTAN A. ABDULALI, B. GANESH BALIGA, ANDREW D. CLAYDEN, and DONALD R. SMITH

The coronary artery luminal diameter of 32 patients with aortic stenosis (AS) were compared by means of a derived index with 24 control subjects without left ventricular (LV) hypertrophy. Patients with AS had significantly larger coronary arteries than control subjects ($p < 0.01$). The increase in coronary luminal diameters had a weak correlation with LV wall thickness ($r = 0.32$) and LV mass ($r = 0.34$). In 21 patients with AS and normal coronary angiograms, there were no significant differences in coronary artery diameters, peak LV stress or LV tension at rest between patients with and those without angina.

454 Detailed Anatomy of the Normally Functioning Aortic Valve in Hearts of Normal and Increased Weight

MARC A. SILVER and WILLIAM C. ROBERTS

The area, weight and 4 linear measurements were made on each aortic valve cusp in 100 necropsy patients with normally functioning aortic valves, and the volume of each sinus of Valsalva and the aortic area at the sinotubular junction were determined in the same patients. The sums of the aortic valve cuspal areas, cuspal weights and sinus of Valsalva volumes increased with age ($p < 0.001$) and with heart weight ($p < 0.001$). All 3 variables (cuspal area, cuspal weight and sinus of Valsalva volume) also increased with age and heart weight relative to each other. The luminal area of aorta at the sinotubular junction also increased with age and heart weight, and it also increased as the sum of the aortic valve cuspal areas and weights and sinus of Valsalva volumes increased. In only 16% of the 100 patients were the 3 aortic valve cusps of similar size (<5% difference in area between cusps); in 51%, 1 cusp was of different size than the other 2, and in 33% of the patients all 3 cusps were of different sizes.

462 Echophonocardiographic Estimates of Pulmonary Artery Wedge Pressure in Mitral Stenosis

PETER S. RAHKO, JAMES A. SHAVER, ROSEMARIE SALERNI, WILLIAM H. GAMBLE, and P. S. REDDY

The accuracy of echophonocardiographic intervals for predicting pulmonary artery wedge (PAW) pressure or left atrial (LA) pressure was reviewed in 77 patients with mitral stenosis. The A_2-E and Q-C intervals were correlated both individually and in combination with PAW and LA pressures. The A_2-E interval correlation with mean PAW pressure was only modest, but improved when combined as a ratio or difference with the Q-C interval or when it was correlated with the V wave of PAW pressure. Atrial fibrillation decreased the predictive accuracy of all intervals. The best correlations were obtained when LA pressure was used, suggesting that damping of the PAW pressure also affects this relation. Thus, multiple factors affect the noninvasive estimates of PAW or LA pressures, but these predictive indexes may give valuable information when used appropriately.

CARDIOMYOPATHY

471 A Randomized Trial of Low-Dose Beta-Blockade Therapy for Idiopathic Dilated Cardiomyopathy

JEFFREY L. ANDERSON, JOAN R. LUTZ, EDWARD M. GILBERT, SHERMAN G. SORENSEN, FRANK G. YANOWITZ, RONALD L. MENLOVE, and MARIAN BARTHOLOMEW

Beta blockade to improve survival in idiopathic dilated cardiomyopathy (IDC) has been controversial, and randomized studies have not been performed. Thus, 50 patients with IDC were randomized and paired to standard therapy (C) alone or with β blockade (BB). Entry characteristics of the 2 groups were similar. Beta blockade with metoprolol was titrated from 12.5 to 50 mg twice daily as tolerated (final average dose 61 mg daily). Clinical follow-up averaged 19 months (range 1 to 38). Low-dose BB was tolerated in 80% of IDC patients on a long-term basis. By intention to treat, 5 BB and 6 C patients died (difference not significant). By actual treatment, 3 BB and 8 C patients died ($p = 0.12$). Functional class and exercise capacity favored those who received BB. IDC patients who received low-dose BB have a good prognosis. However, mortality in C patients is less than in retrospective studies. A larger, randomized multicenter study will be required for definitive evaluation of survival effects of BB in patients with IDC.

476 Two-Dimensional Echocardiographically Guided Pericardiocentesis: Experience in 117 Consecutive Patients

JOHN A. CALLAHAN, JAMES B. SEWARD, RICK A. NISHIMURA, FLETCHER A. MILLER, Jr., GUY S. REEDER, CLARENCE SHUB, MARK J. CALLAHAN, THOMAS T. SCHATTENBERG, and A. JAMIL TAJIK

Pericardiocentesis guided by 2-dimensional echocardiography provides a safe and efficient way to remove pericardial fluid. It can be carried out as an emergency procedure and is versatile enough to satisfy routine diagnostic needs.

480 Magnetic Resonance Imaging of Constrictive Pericardial Disease

RENATE L. SOULEN, DAVID D. STARK, and CHARLES B. HIGGINS

Gated magnetic resonance imaging of 5 patients with suspected constrictive pericardial disease was performed using a superconducting magnet and compared with other noninvasive studies and with hemodynamic data. Hemodynamic data at catheterization in all patients was consistent with pericardial constriction. Pericardial thickness measured >5 mm in 4 patients and 5 mm in 1 patient with constrictive pericardial disease. Calcific deposits produced no magnetic resonance signal, whereas pericardial inflammation caused increased signal intensity of the thickened pericardium. Dilatation of the right atrium, vena cavae and hepatic veins and right ventricular narrowing was present in all patients. Magnetic resonance allows measurement of pericardial thickness *and* depicts internal cardiac anatomy without using radiation or contrast medium. This early experience suggests it is the imaging method of choice in the diagnosis of constrictive pericardial disease.

485 The King of Hearts: Analysis of 23 Patients with Hearts Weighing 1,000 Grams or More

WILLIAM C. ROBERTS and MICHAEL J. PODOLAK

Certain clinical and morphologic features are described in 23 patients in whom the heart at necropsy weighed ≥1,000 g (mean 1,106). The heart weight to body weight ratio ranged from 1.2 to 2.7 (normal 0.40). The 23 patients were derived from examination of the hearts of 7,671 patients with various cardiovascular disorders in a 25-year period. The massive cardiomegaly was the result of aortic regurgitation (AR) in 14 patients (61%): isolated in 8, associated with mitral regurgitation in 4, and associated with ventricular septal defect in 2. Three others (13%) had combined aortic valve stenosis and aortic regurgitation and 1 patient (4%) had mitral stenosis and regurgitation and mild aortic stenosis. Four patients (17%) had hypertrophic cardiomyopathy, and 1 patient (4%) had ventricular septal defect with mitral stenosis. They were 20 to 64 years old (mean 42) and 21 (91%) were men. Four patients at necropsy had 1 or more major coronary arteries narrowed >75% in cross-sectional area by atherosclerotic plaques, and only 4 patients had grossly visible left ventricular (LV) scars, 2 of whom had insignificant coronary narrowing. Examination of electrocardiograms in 17 of the 23 patients disclosed that Sokolow-Lyon criteria for LV hypertrophy was achieved in only 12 patients (71%) and Romhilt-Holt QRS voltage criteria faired even worse. Total 12-lead QRS voltage was >175 mm (10 mm = 1 mV) in 16 patients (94%) and >250 mm in 13 patients (76%). The total 12-lead QRS voltage in 17 patients ranged from 140 to 601 mm (mean 323). Measurement of the sum of 12-lead QRS voltage may be quite useful in diagnosing LV hypertrophy by electrocardiogram.

495 Detection of Platelet Deposition at the Site of Peripheral Balloon Angioplasty Using Indium-111 Platelet Scintigraphy

CHRISTOPHER F. POPE, MICHAEL D. EZEKOWITZ, EILEEN O. SMITH, STANLEY RAPOPORT, MORTON GLICKMAN, H. DIRK SOSTMAN, and BARRY L. ZARET

To determine whether platelet deposition at the site of balloon angioplasty could be detected using indium-111 platelet scintigraphy, 15 patients aged 60 ± 9 years (mean ± standard deviation) undergoing iliac or femoral (n = 12), renal (n = 2) and distal aortic (n = 1) dilatations were studied. All patients received intravenous heparin at time of dilatation. In 11 of 12 patients with iliac and/or femoral dilatations, focal uptake was observed. In 4 patients (2 with renal artery stenoses, 1 iliofemoral and 1 distal aortic) uptake at the dilatation site was not detect-

Small Wonder

Our challenge was to build a compact, portable cardiac ultrasound laboratory, with state-of-the-art performance and deliver it at a cost-effective price. The result: the new SSH-60A.

We began with a compact, lightweight and highly mobile design. Added the high performance of phased array transducer technology, and an extensive range of probes to perform a wide variety of routine and special procedures . . . from tiny neonates to large-chested adults.

The SSH-60A incorporates a powerful on-board computer with sophisticated, "user friendly" software to provide a comprehensive range of functions either on- or off-line. There's two frame memory for recording and displaying both B- and M-modes singly or simultaneously. Complete calculation of all important cardiac parameters (SV, EF, FS, CO and more). Full alphanumerics plus comprehensive exam data, physiological parameters with ECG synchronization and A-mode/TGC displays, only cite a few of the SSH-60A's features.

Couple all of its capability with easy upgradability to Doppler *and* a surprisingly affordable price. We think you'll agree that the SSH-60A is today's "small wonder" in cardiac ultrasound.

For further information on the SSH-60A cardiac scanner, please call toll-free (800) 421-1968, in California call (714) 730-5000, or write Toshiba Medical Systems, 2441 Michelle Drive, Tustin, CA 92680.

FIRST LINE OF DEFENSE

CITRUS FRUIT-PUNCH

Unmatched safety of liquids, in convenient forms and strengths *and* pleasant-tasting flavors.

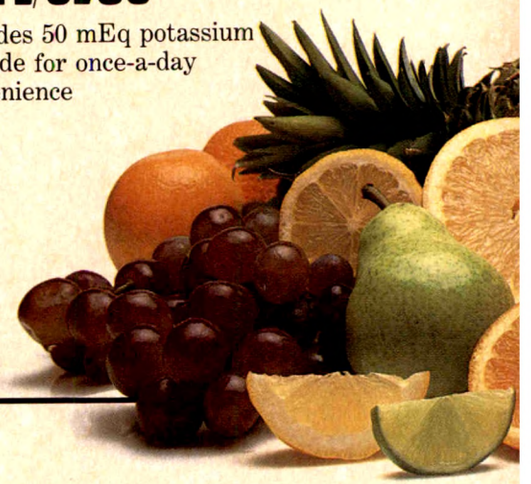
K-LYTE/CL®

When your patients need cl – ion.

- effervescent tablets with delicious citrus or fruit-punch flavor
- each tablet in solution provides 25 mEq potassium chloride

K-LYTE/CL® 50

- provides 50 mEq potassium chloride for once-a-day convenience



K-LYTE/CL®

Caution: Federal Law Prohibits Dispensing Without Prescription

K-Lyte/Cl® 50 Each tablet in solution provides the equivalent of 50 mEq (3730 mg) potassium chloride (supplied by 2.24 gm potassium chloride, 2.0 gm potassium bicarbonate and 3.65 gm L-lysine monohydrochloride) and 1.0 gm citric acid.

K-Lyte/Cl® Each tablet in solution provides the equivalent of 25 mEq (1865 mg) potassium chloride (supplied by 1.5 gm potassium chloride, 0.5 gm potassium bicarbonate and 0.91 gm L-lysine monohydrochloride) and 0.55 gm citric acid.

DESCRIPTION

K-Lyte/Cl 50 and K-Lyte/Cl are oral potassium and chloride supplements. Each K-Lyte/Cl® 50 mEq tablet in solution provides the equivalent of 50 mEq (3730 mg) potassium chloride (supplied by 2.24 gm potassium chloride, 2.0 gm potassium bicarbonate and 3.65 gmL-lysine monohydrochloride) and 1.0 gm citric acid.

Each K-Lyte/Cl® tablet in solution provides the equivalent of 25 mEq (1865 mg) potassium chloride (supplied by 1.5 gm potassium chloride, 0.5 gm potassium bicarbonate and 0.91 gm L-lysine monohydrochloride) and 0.55 gm citric acid.

INDICATIONS AND USAGE

All K-Lyte® products are used for therapy or prophylaxis of potassium deficiency. They are useful when thiazide diuretics, corticosteroids, or vomiting and diarrhea cause excessive potassium loss; and when dietary potassium is low. These products may also be useful when potassium therapy is indicated in digitalis intoxication. K-LYTE/Cl and K-LYTE/Cl 50 are recommended in the management of hypokalemia accompanied by metabolic alkalosis and hypochloremia, e.g., as induced by vomiting.

CONTRAINDICATIONS

Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions; chronic renal impairment, metabolic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns or adrenal insufficiency. Hypokalemia should not be treated by the concomitant administration of potassium salts and potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

WARNINGS

In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and may be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

PRECAUTIONS

General precautions — The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. When interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of reduced total body potassium. Therefore, the treatment of potassium depleti requires careful attention to acid-base balance and appropriate monitoring of serum electroly the ECG, and the clinical status of the patient.

Information for Patients

To minimize the possibility of gastrointestinal irritation associated with the oral ingestio concentrated potassium salt preparations, patients should be carefully directed to dissolv dose completely in the stated amount of water.

Laboratory Tests

Frequent clinical evaluation of the patient should include ECG and serum potassium determinations.

Drug Interactions

The simultaneous administration of potassium supplements and a potassium-sparing diuretic produce severe hyperkalemia (see Contraindications).

Potassium supplements should be used cautiously in patients who are using salt substitu because most of the latter contain substantial amounts of potassium. Such concomitant use co result in hyperkalemia.

Usage in Pregnancy

Pregnancy Category C — Animal reproduction studies have not been conducted with any of t K-LYTE products. It is also not known whether these products can cause fetal harm wh administered to a pregnant woman or can affect reproduction capacity. They should be given a pregnant woman only if clearly needed.

Nursing Mothers

Many drugs are excreted in human milk and because of the potential for serious adverse react in nursing infants from oral potassium supplements, a decision should be made whether discontinue nursing or discontinue the drug, taking into account the importance of the d the mother.

Usage in Children

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

The most common adverse reactions to oral potassium supplements are nausea, vomiting, dia and abdominal discomfort. These side effects occur more frequently when the medicatio taken with food or is not diluted properly or dissolved completely.

Hyperkalemia occurs only rarely in patients with normal renal function receiving potassi supplements orally. Signs and symptoms of hyperkalemia are cardiac arrhythmias, ment confusion, unexplained anxiety, numbness or tingling in hands, feet or lips, shortness of or difficult breathing, unusual tiredness or weakness and weakness or heaviness of legs Contraindications, Warnings and Overdosage).

How Supplied

K-Lyte/Cl® Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30, and 250. K-Lyte/Cl® 50 Effervescent Tablets (citrus or fruit punch flavors) are available in ca of 30 and 100. Each tablet is individually foil wrapped.

ed. Thus, despite the use of intravenous heparin, platelet accumulation at the site of peripheral angioplasty was detected using indium-111 platelet scintigraphy in most patients. These preliminary data illustrate the potential value of indium-111 platelet scintigraphy in the assessment of local platelet deposition in the restenosis process.

...and protecting healing hearts in the months ahead

The combination of early intravenous administration of Lopressor followed by long-term oral therapy resulted in a 36% reduction of three-month mortality in patients with definite or suspected acute MI in the Göteborg Trial.[1]

Treatment should be continued for 1-3 years.

Lopressor is contraindicated in patients with a heart rate <45 beats/min; significant heart block greater than first degree (P-R interval ≥0.24 sec); systolic blood pressure <100 mmHg; or moderate-to-severe cardiac failure. Please see last page for Brief Summary of Prescribing Information.

Lopressor®
metoprolol tartrate **Tablets Ampuls**

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
Myocardial Infarction
Lopressor ampuls and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; significant heart block greater than first degree (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first-(P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent $beta_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a $beta_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and $beta_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should know how they react to this medicine before they operate automobiles and machinery or engage in other tasks requiring alertness. Patients should contact the physician if any difficulty in breathing occurs, and before surgery of any type, the patient should inform the physician or dentist that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a 1-year study in dogs, there was no evidence of drug-induced toxicity at or below oral dosages of 105 mg/kg per day. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.
Pregnancy Category B
Reproduction studies have been performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg and have revealed no evidence of impaired fertility or teratogenicity due to Lopressor. Increased postimplantation loss and decreased neonatal survival did occur in the rats (threshold between 50 and 500 mg/kg), and distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

DOSAGE AND ADMINISTRATION
Myocardial Infarction
Early Treatment: During the early phase of definite or suspected acute myocardial infarction, treatment with Lopressor can be initiated as soon as possible after the patient's arrival in the hospital. Such treatment should be initiated in a coronary care or similar unit immediately after the patient's hemodynamic condition has stabilized.

Treatment in this early phase should begin with the intravenous administration of three bolus injections of 5 mg of Lopressor each; the injections should be given at approximately 2-minute intervals. During the intravenous administration of Lopressor, blood pressure, heart rate, and electrocardiogram should be carefully monitored.

In patients who tolerate the full intravenous dose (15 mg), Lopressor tablets, 50 mg every 6 hours, should be initiated 15 minutes after the last intravenous dose and continued for 48 hours. Thereafter, patients should receive a maintenance dosage of 100 mg twice daily (see ***Late Treatment*** below).

Patients who appear not to tolerate the full intravenous dose should be started on either 25 mg or 50 mg every 6 hours (depending on the degree of intolerance) 15 minutes after the last intravenous dose or as soon as their clinical condition allows. In patients with severe intolerance, treatment with Lopressor should be discontinued (see **WARNINGS**).

Late Treatment: Patients with contraindications to treatment during the early phase of suspected or definite myocardial infarction, patients who appear not to tolerate the full early treatment, and patients in whom the physician wishes to delay therapy for any other reason should be started on Lopressor tablets, 100 mg twice daily, as soon as their clinical condition allows. Therapy should be continued for at least 3 months. Although the efficacy of Lopressor beyond 3 months has not been conclusively established, data from studies with other beta blockers suggest that treatment should be continued for 1-3 years.

Note: **Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.**

Medically Directed At-Home Rehabilitation Soon After Clinically Uncomplicated Acute Myocardial Infarction: A New Model for Patient Care

ROBERT F. DeBUSK, MD, WILLIAM L. HASKELL, PhD, NANCY H. MILLER, RN, KATHY BERRA, RN,* and CRAIG BARR TAYLOR, MD, *In Cooperation with* WALTER E. BERGER III, MD, *and* HENRY LEW, MD

Medically directed at-home rehabilitation was compared with group rehabilitation which began 3 weeks after clinically uncomplicated acute myocardial infarction (AMI) in 127 men, mean age 53 ± 7 years. Between 3 and 26 weeks after AMI, adherence to individually prescribed exercise was equally high (at least 71%), the increase in functional capacity equally large (1.8 ± 1.0 METs) and nonfatal reinfarction and dropout rates equally low (both 3% or less) in the 66 men randomized to home training and the 61 men randomized to group training. No training-related complications occurred in either group. The low rate of reinfarction and death (5% and 1%, respectively) in the study as a whole, which included 34 patients with no training and 37 control patients, reflected a stepwise process of clinical evaluation, exercise testing at 3 weeks and frequent telephone surveillance of patients who underwent exercise training. Medically directed at-home rehabilitation has the potential to increase the availability and to decrease the cost of rehabilitating low-risk survivors of AMI.

(Am J Cardiol 1985;55:251–257)

Early evaluation of prognosis after acute myocardial infarction (AMI) has in recent years emerged as an important focus of standard medical care for this condition. Exercise testing performed alone or in conjunction with radionuclide imaging techniques effectively distinguishes high-risk and low-risk patients 10 to 21 days after AMI.[1–6] The use of early exercise testing to identify very low risk patient subsets (i.e., mortality rate less than 2% after AMI[1–3]), enables earlier rehabilitation of these patients. In a previous study from this laboratory, the functional capacity of patients who underwent medically supervised group exercise training 3 to 11 weeks after clinically uncomplicated AMI exceeded that of control subjects with no training.[7] The present study was designed to determine whether exercise training performed at home 3 to 26 weeks after clinically uncomplicated AMI was as safe and effective as medically supervised group training.

Address for reprints: Robert F. DeBusk, MD, Stanford Cardiac Rehabilitation Program, 730 Welch Road, Palo Alto, California 94304.

Methods

Patients: Patients were admitted to Kaiser Permanente hospitals in Redwood City and Santa Clara, California between July 1, 1979 and July 1, 1983. AMI was documented by the combination of characteristic elevation of serum creatine kinase or oxaloacetic transaminase, a history of prolonged chest pain consistent with AMI and the appearance of new Q waves or evolutionary ST changes. Of the 378 consecutive men aged 70 years or younger considered for the study, 175 were excluded because of conditions that precluded symptom-limited treadmill testing 3 weeks after AMI: cardiac exclusions in 112 patients for congestive heart failure, unstable angina pectoris, valvular heart disease, atrial fibrillation, bundle branch block, and a history of coronary artery bypass surgery; noncardiac exclusions in 38 patients for stroke, limiting orthopedic abnormalities, peripheral vascular disease, chronic obstructive pulmonary disease and obesity, and patient or physician refusal in 10 and 15 patients, respectively.

The remaining 203 patients considered eligible to undergo symptom-limited treadmill testing 3 weeks after AMI were randomized to 1 of 6 groups that represented 4 basic assignments (Fig. 1): exercise testing followed by exercise training at home for a duration of 23 weeks (extended training—group 1A) or 8 weeks (brief training—group 1B), or in a gymnasium for 23 weeks (extended training—group 2A) or 8 weeks (brief training—group 2B), exercise testing without subsequent exercise training (group 3) and control (neither exercise testing nor training—group 4).

Five patients were excluded after randomization because of moderately severe angina or signs of congestive heart failure during treadmill exercise testing. Of these, 3 underwent coronary artery bypass surgery, 1 experienced nonfatal reinfarction and 1 had no subsequent cardiac event.

The 161 patients who remained in the trial after 3 weeks of exercise testing and the 37 control patients constitute the training study. Exercise testing was scheduled for all but control patients 11 weeks after AMI and for all patients 26 weeks after AMI.

The mean age of the 198 training study participants was 52 ± 9 years. Infarction was inferior in 54%, anterior in 31% and transmural in 15% of patients. A history of old infarction or angina pectoris 3 months or more before AMI was noted in 7 and 24% of patients, respectively. Before AMI, 14% of the patients were retired. The remaining 86% were employed in the following categories: professional/mangerial, 56%; clerical/sales, 15%; and manual labor, 15%. Medical and demographic characteristics were not significantly different among the groups.

Among patients who underwent exercise testing at 3 weeks, the proportion receiving β-blocking drugs, long-acting nitrates and antiarrhythmic medications (procainamide, quinidine and disopyramide) was 11, 17 and 6%, respectively, without significant intergroup differences. The proportion of patients who received these medications at 26 weeks was 24, 22 and 11%, respectively, without significant intergroup differences. On both occasions these drugs were discontinued 48 to 72 hours before testing.

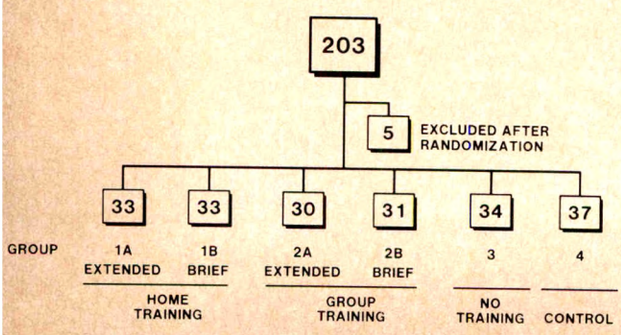

FIGURE 1. Random assignment of subjects.

Exercise testing: Symptom-limited treadmill testing was performed using protocols described by Naughton et al,[8] with 12-lead electrocardiographic monitoring and blood pressure recording by cuff sphygmomanometer. Exercise was terminated by: (1) limiting symptoms of chest pain, dyspnea, fatigue or leg cramps; (2) hypotension (a decrease in systolic pressure of at least 10 mm Hg from the peak value attained earlier during exercise); or (3) ventricular tachycardia (3 consecutive premature ventricular complexes). No complications in exercise testing occurred.

Patient counseling: After exercise testing at 3 weeks, patients and their spouses met with the program physician for 30 to 45 minutes to discuss the implications of the exercise test for further management. The patients were advised that test results would be provided to their private physicians who would retain responsibility for their medical management. The patients' capacity to resume customary preinfarctional physical activities with safety was discussed in detail. Patients and spouses then met with the program nurse for 30 to 45 minutes to discuss medication adherence and adverse effects, smoking, dietary habits and sexual activity. Patients assigned to home or group training were instructed by the nurse in carrying out their individualized exercise plan. "No-training" patients received no specific exercise prescription.

Exercise training prescription: The training heart-rate range for group and home training was 70 to 85% of the peak treadmill heart rate achieved at 3 and 11 weeks. Because peak exercise heart rate increases significantly by the seventh week after clinically uncomplicated AMI,[7] the training heart-rate range during weeks 8 to 11 was based on 100% of the peak 3-week treadmill heart rate or 85% of age-predicted peak heart rate, whichever was less. The average training range 3 to 7, 8 to 11 and 11 to 26 weeks was 96 to 117 , 105 to 121 and 110 to 129 beats/min, respectively. At 11 weeks, exercise cycles and heart rate monitors were withdrawn from patients assigned to brief home training, and paid participation in the YMCArdiac Therapy Program was terminated for patients who underwent brief group training.

Home training: Patients received detailed, written instructions involving all aspects of the home training program, including recognition of important changes in clinical status, such as worsening of angina pectoris and the appearance of unusual dyspnea or other conditions precluding exercise training. In the event of a change in clinical status, patients were advised to defer exercise training and to contact the program nurse or private physician.

Patients assigned to home training who were free of treadmill angina at 3 weeks (n = 55) were loaned stationary cycles (Tunturi), whereas those with treadmill angina at 3 weeks (n = 11) were instructed to walk briskly. All patients were instructed to exercise continuously for 30 minutes, 5 days/week. Exercise training sessions consisted of 5 minutes of warm-up, 20 minutes within the prescribed training heart-rate range and 5 minutes of cool-down.

Patients were loaned portable ExerSentry heart rate monitors (Respironics, Inc., Monroeville, Pennsylvania) to assist them in remaining within their prescribed heart-rate range during home training. These devices emit an audible tone whenever the heart rate is above or below the preset range and remain silent when the heart rate is within this range. A portable CardioBeeper monitor (Survival Technology, Inc.,

Bethesda, Maryland) was used to transmit the electrocardiogram over the telephone to a strip-chart recorder located in the research unit. At prearranged times twice weekly, the program nurse telephoned patients at home to transmit an M-CL5 bipolar lead electrocardiogram during 1 minute of exercise within the training heart-rate range and during 1 minute of immediate recovery.

These telephone calls permitted verification of the training intensity and detection of changes in patients' clinical status and medication use. Adherence to training was also evaluated by the nurse's review of daily exercise training logs. These logs, which included duration and intensity of training as judged from heart rates displayed on ExerSentry monitors, were mailed to the program nurse every 2 weeks. No complications of home exercise training occurred.

Group training: Under the supervision of 2 nurses or 1 nurse and 1 physician, patients exercised with 20 to 35 other cardiac patients in the YMCArdiac Therapy programs in Palo Alto and San Jose, California. Three 1-hour training sessions per week were divided among 10 to 15 minutes of warm-up calisthenics, 30 to 40 minutes of walk/jog conditioning cycling and 10 to 15 minutes of cool-down walking and stretching, producing the same total duration of exercise within the training range as for home training (i.e., approximately 100 min/week). Guidelines for increasing the intensity of group training at 8 and 11 weeks were identical to those for home training. The program staff documented patients' participation in a manner similar to that for home training: training heart rate and exercise duration, medication use, clinical status and reasons for no attendance were tabulated. Electrocardiographic monitoring was not routinely performed; no complications of group exercise training occurred.

Documentation of nonprescribed exercise: Patients were interviewed at 11 and 26 weeks concerning the frequency and duration of walking and the intensity and duration of other aerobic-type leisure activities since hospitalization or their last clinic visit. To avoid influencing their physical activity habits, control patients were interviewed only at 26 weeks.

Data were collected separately for nonprescribed walking (i.e., equivalent to a workload of less than 4 METs, which would not be expected to lead to a training effect) and for more vigorous nonprescribed exercise (i.e., 4 METs or more, which would be expected to lead to such an effect).[9] The intensity of the latter was approximated from the known energy cost of various activities.[10] The total amount of exercise performed was calculated as MET minutes per day. For example, a patient who performed 10 minutes of a 5-MET activity was judged to have completed a total of 50 MET minutes of activity. The same method was used to quantitate prescribed home and group training.

Data analysis: Comparisons of the exercise test responses among groups and changes that occurred in the interval of 3 to 26 weeks were performed by analysis of variance. Correlational analysis was used to evaluate the relation between changes in functional capacity and adherence to exercise training. Differences or associations were considered to be significant if p values were <0.05.

Results

Treadmill-induced ischemia and arrhythmia: The overall incidence of treadmill-induced ischemic ST-segment depression of at least 0.1 mV or angina pectoris was 29% (47 of 161 patients) at 3 weeks: 20 patients had angina and ischemic depression, 22 had ischemic depression without angina and 5 had angina without ischemic depression. The frequency of these ischemic abnormalities was not significantly different among groups (Table I). Of the 42 patients with ischemic ST-segment depression of at least 0.1 mV, 10 (24%) manifested "marked" ischemic ST-segment depression of at least 0.2 mV at a heart rate of 135 beats/min or less—a combination that is associated with an increased risk of subsequent cardiac events in patients similar to those in the present study.[3] The overall incidence of treadmill-induced ischemic ST-segment depression of at least 0.1 mV or angina pectoris at 26 weeks was 28% (45 of 160 patients) without significant intergroup differences (Table I).

Treadmill-induced ventricular tachycardia was absent in the 52 patients (32%) who demonstrated treadmill-induced ventricular bigeminy or couplets at 3 weeks. No significant intergroup differences in the frequency of these complex arrhythmias were noted.

Cardiac events: No significant intergroup differences in the rate of cardiac events were noted. Of the 198 training study participants, including 37 control patients who did not undergo 3-week treadmill testing, 28 (14%) experienced cardiac events between 3 and 26 weeks: sudden cardiac death in 2, nonfatal reinfarction in 10, coronary artery bypass surgery in 12, rehospitalization for worsening angina pectoris in 2 and congestive heart failure in 2. Half of these events occurred between 3 and 11 weeks and half between 11 and 26 weeks. Both sudden cardiac deaths (i.e., within 1 hour of the onset of symptoms) occurred between 11 and 26 weeks—1 in a control patient and 1 in a no-training patient. Of the 12 patients who underwent surgery, 3-vessel coronary artery disease was present in 9.

Eight patients refused to continue participation after enrollment in the training study: 2 control patients, 4 no-training and 2 home-training patients. Follow-up to 26 weeks was obtained in all of these patients, 1 of whom underwent coronary artery bypass surgery and 1 experienced nonfatal reinfarction. Two additional patients who moved from the area were lost to follow-up. Thus, of the 198 patients who entered the training study at 3 weeks, 160 (81%) remained in the study at 26 weeks.

Of the 161 patients who underwent treadmill testing at 3 weeks, the incidence of cardiac events 3 to 26 weeks after infarction was significantly greater in those with

Group training				
Brief	6.2 ± 1.0	1.4 ± 1.4*	0.2 ± 1.2	7.9 ± 1.3†,‡
Extended	6.6 ± 1.3	1.4 ± 1.3*	0.6 ± 1.1	8.9 ± 1.4†,‡
No-training patients	6.1 ± 1.5	0.8 ± 1.0	0.4 ± 1.0	7.5 ± 1.8
Control patients	—	—	—	7.0 ± 1.7

* $p < 0.05$ vs values in the no-training patients; † $p < 0.05$ vs values in the no-training patients; ‡ $p < 0.001$ vs values in control patients. All values are expressed as mean ± standard deviation. Δ = change in functional capacity; — = not done.

treadmill-induced ischemic ST-segment depression of at least 0.1 mV or angina pectoris than in those without this abnormality: 10 of 47 (22%) vs 11 of 114 (10%) ($p < 0.05$). A substantially higher incidence of subsequent cardiac events was noted in patients with marked ischemic ST-segment depression of at least 0.2 mV at a heart rate of ≤135 beats/min than in those without this combination: 7 of 10 (70%) vs 14 of 151 (9%) ($p < 0.001$).

Adherence to prescribed exercise training: Adherence to home or group training was expressed as the ratio of exercise sessions completed to those prescribed. Adherence between 3 and 11 weeks was 89% for home training and 84% for group training (difference not significant). Adherence between 11 and 26 weeks decreased significantly ($p < 0.05$) to 72 and 71% for home- and group-training groups, respectively.

Nonprescribed physical activity: The total duration of nonprescribed walking per day, from 3 to 26 weeks, was similar for training and no-training patients, (approximately 30 ± 32 min/day) and was slightly higher in control patients (45 ± 44 min/day) (difference not significant). The total amount of more vigorous nonprescribed activity (i.e., 4 METs or more between 3 and 11 weeks) was greater in no-training than in home- or group-training patients: Because of the large inter-individual variation among no-training patients, this difference was not statistically significant (Fig. 2).

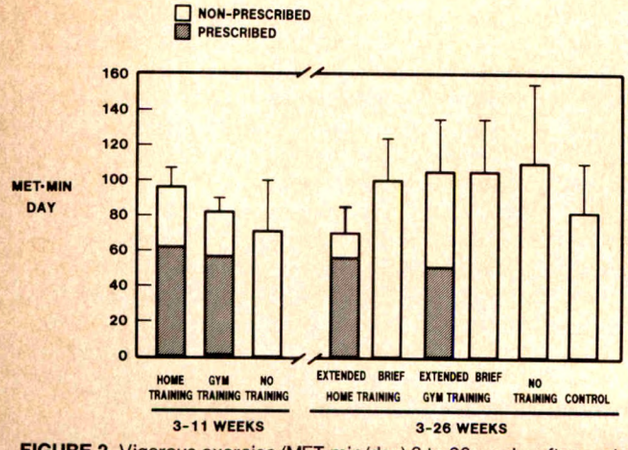

FIGURE 2. Vigorous exercise (MET·min/day) 3 to 26 weeks after acute myocardial infarction (POST-MI). Values are expressed as mean ± standard error of the mean.

Total vigorous exercise: Total vigorous daily exercise, both prescribed and nonprescribed, performed by patients who underwent home or group training between 3 and 11 weeks was not significantly greater than the total of such exercise performed by no-training patients (Fig. 2). No significant intergroup differences in total daily vigorous exercise were noted between 11 and 26 weeks.

Changes in functional capacity 3 to 26 weeks after infarction: The average increase in functional capacity (i.e., peak treadmill workload in METs) between 3 and 26 weeks was significantly greater ($p < 0.05$) in training groups than in the no-training groups (1.8 vs 1.2 METs, respectively) (Table II). Most of this increase occurred between 3 and 11 weeks. Overall, home- and group-training patients demonstrated a 35% increase in functional capacity between 3 and 26 weeks, compared with 23% for no-training patients.

Exercise-induced abnormalities during home training: Of the 66 patients who began home training, 20 demonstrated ventricular arrhythmias on the brief telephone transmissions: isolated premature ventricular contractions in 14, bigeminy in 5 and couplets in 1. Antiarrhythmic therapy was instituted in the patient with couplets and in 1 of the patients with bigeminy. No patient with exercise-induced premature ventricular contractions was withdrawn from the study and none experienced cardiac events.

Exercise-induced ischemic ST-segment depression less than 0.2 mV was observed in 4 patients, all of whom had demonstrated at least 0.1 mV of treadmill-induced ischemic ST-segment depression at 3 weeks. No patient was withdrawn from the study solely because of exercise-induced ischemic ST-segment depression. Three patients who experienced an increasing frequency or intensity of anginal symptoms between 3 and 26 weeks were referred to their physicians by the nurse for further evaluation. At 3 weeks, all 3 patients had demonstrated mild treadmill angina and marked ischemic ST-segment depression as previously defined. Two patients underwent coronary artery surgery and 1 resumed exercise training after treatment with β-blocking drugs.

Exercise-induced abnormalities detected during group training: Of the 61 patients who commenced group training, 2 were referred to their physicians for

antiarrhythmic therapy on the basis of episodes of bigeminy and couplets recorded during exercise sessions; palpitation prompted brief transthoracic electrocardiographic monitoring through defibrillator paddles. Palpitation was unaccompanied by chest pain or dizziness and both patients resumed exercise training. No patient was referred to his physician because of increasing episodes of angina during the training sessions and no patient was withdrawn from the study for this reason.

Discussion

The medically directed at-home rehabilitation program described here represents a new model for augmenting the functional capacity of low-risk patients at a time when physician and patient alike share a concern that physical activity may precipitate subsequent cardiac events. The low rate of cardiac events observed in the present study (1% mortality, 6% combined death and reinfarction and 14% total events) reflects, in part, the identification of a low-risk population by means of historical and clinical characteristics and treadmill exercise testing.[3] The 203 patients who were considered eligible for symptom-limited treadmill testing 3 weeks after myocardial infarction represent 54% of the total population.

Since subsequent cardiac events occurred in 4 of the 5 patients who were excluded from the training study because of severe treadmill-induced angina or heart failure, this exclusion seems appropriate. Of the 161 men who were entered into the training study after 3-week treadmill testing, 10 had prognostically important ischemic ST-segment depression (0.2 mV or greater at a heart rate of ≤135 beats/min,[3] 7 of whom experienced subsequent cardiac events: rehospitalization for increasingly severe angina pectoris in 5 and nonfatal reinfarction in 2. Thus, of the 166 men who underwent treadmill testing, including the 5 who were excluded from the training study, 25 experienced subsequent cardiac events, 11 (44%) of whom demonstrated severe abnormalities during treadmill testing. Prompt cardiac catheterization and consideration of coronary artery surgery may be appropriate in patients with severe treadmill-induced ischemic abnormalities.

In patients with less severe ischemia on treadmill testing at 3 weeks, continued surveillance provides an alternative to immediate cardiac catheterization: Among patients without severe angina or "high-risk" ischemic ST-segment depression during treadmill testing, the incidence of cardiac events was low (3 of 37, or 8%). None of these cardiac events was fatal.

Participation in home training resulted in more intensive medical surveillance than is standard in most communities. Patients in the present study visited their physicians an average of twice in the first 11 weeks and once thereafter. In contrast, telephone contact, including brief exercise electrocardiographic transmissions, occurred 16 and 46 times, respectively, in patients completing brief and extended home training. The extended surveillance provided by the nurse's frequent telephone contact with the patient may have contributed to the low rate of cardiac events observed in patients who underwent home training. The 3 patients who reported an increasing frequency or intensity of anginal symptoms during the telephone contacts were referred to their physicians for further evaluation. The ease of communication afforded by regular contact appeared to facilitate patients' reports of a change in their pattern of chest pain. No patient who died suddenly had an opportunity to receive prolonged surveillance.

The risk of exercise-induced cardiac arrest in patients with ischemic heart disease is related to the intensity of exercise training. Most such episodes occur at heart rates exceeding the prescribed range.[11] Maintaining the training heart rate within the prescribed range during home exercise was reliably accomplished by the use of portable monitors that alerted patients to excessive heart rates. The intensity of exercise training between 3 and 11 weeks, as judged from the training heart rate range of 96 to 121 beats/min, was somewhat lower than the rate generally used for exercise training in patients with chronic ischemic heart disease.[12] Despite this, patients who underwent home or group training demonstrated a 50% greater increase in functional capacity between 3 and 26 weeks than was observed in the no-training patients: 1.8 vs 1.2 METs ($p < 0.05$); most of this increase occurred by 11 weeks.

This comparison underestimates the impact of prescribed exercise training on functional capacity, for the no-training patients were unexpectedly active, especially in the early recovery period 3 to 11 weeks after AMI. Through exercise testing and the counseling that followed, these patients received substantial reassurance concerning their ability to resume their customary activities with safety. The total amount of daily vigorous nonprescribed exercise performed 3 to 11 weeks after AMI was slightly greater in the no-training patients than in those who underwent training and was not significantly less than the total amount of prescribed and nonprescribed physical activity performed by patients at home or in group training. The present study corroborates earlier observations from this laboratory that treadmill testing followed by a thorough explanation of exercise test results tends to enhance physical activity in the early period after clinically uncomplicated AMI.[13] At 26 weeks the peak functional capacity of control patients, who had no exercise testing, counseling or prescribed exercise was 1 to 2 METs lower than that of patients who underwent training ($p < 0.001$).

It is reasonable to ask whether the relatively small absolute difference in functional capacity between training and no-training patients justifies the elaborate program of surveillance and monitoring that was undertaken. The absence of training-related complications makes many of the precautions of home training seem unwarranted in hindsight. However, the present study was concerned not only with safety but with patient satisfaction.

Patient satisfaction was closely related to the extent of contact with the professional staff, especially the nurse. The 95% rate of enrollment of medically eligible

patients (175 of 185) far exceeds that observed in community rehabilitation programs, and obviates 1 of the major problems in research in rehabilitation after AMI (i.e., a selection bias favoring more highly motivated patients). The 71% or greater level of adherence to prescribed exercise training noted in this study, even between 11 and 26 weeks, is far greater than that reported in most previous studies of training after AMI.[14,15] Finally, the rate of refusal to continue further in the training study was substantially lower in training than in no-training or control patients. Of the 8 patient refusals, 6 occurred in the no-training and control patients: 4 in the former and 2 in the latter. The support and encouragment provided by the nurse appeared to contribute to the high rate of adherence and low rate of refusal in patients who underwent home and group training. Patients who participated in home training enjoyed continuing contact with the same nurse who participated in the initial exercise testing and counseling. This afforded an opportunity for patients to receive further information about their condition, ongoing encouragement of exercise training and risk factor modification, and ready access to the medical system in case of a change in clinical status.

Group rehabilitation programs offer not only augmentation of functional capacity, but enhancement of psychologic status,[16] and help in controlling risk factors such as smoking[17] and hyperlipidemia.[18] However, except for peer support and immediately available cardiac resuscitation, these services are also effectively provided in the context of at-home rehabilitation.[19–21] At-home rehabilitation incorporating frequent contact with medical personnel appears to be a feasible alternative to group exercise-training programs for clinically low-risk patients after AMI. Patients with more severe clinical manifestations of disease may require on-site medical supervision of exercise training.

Medically directed at-home rehabilitation has the potential to increase the convenience and availability of rehabilitative services for patients after AMI. Many patients choose not to enroll in group programs for personal or financial reasons, and others quickly drop out because of the inconvenience of commuting to a group training facility.[15,22] Patients who underwent group training spent an average of 100 min/week in transit to and from the exercise facility—an amount that approximated the time spent by patients within the prescribed training range at home. Moreover, access to medically supervised group programs tends to be limited to larger communities.

The at-home rehabilitation program described here should be considered a research prototype, which was designed to safeguard patient safety and to assure adherence and physiologic efficacy. Simplifying the regimen may assure its clinical efficacy without compromising its safety. Further research is required to determine which form of at-home rehabilitation is most cost-effective. Three months of at-home rehabilitation using the equipment and methods described in this study could be offered for little more than $300 per patient (see Appendix)—an amount that many patients may be willing to pay out of pocket if necessary.

The present study suggests that nearly half of the 600,000 Americans who survive an AMI each year may be capable of safely completing 3 months of at-home rehabilitation—nearly 3 times the number of patients after AMI currently undergoing rehabilitation in group programs.

Acknowledgment: We are grateful to the members of the medical staffs of Kaiser Permanente hospitals in Redwood City and Santa Clara who referred patients for this project, and the staffs of the YMCArdiac Therapy Programs in Palo Alto and San Jose who provided exercise training. We gratefully acknowledge the assistance of Helena Kraemer in study design and statistical analysis, Debra Barnes in data analysis, Dorothy Potter in manuscript preparation and Lynda Fisher and Margaret Chandler for technical assistance.

Appendix

Comparative costs of group and at-home rehabilitation programs: The median cost per session of medically supervised group exercise programs during the first 12 weeks of participation is $20.00 (range $9.00 to $69.00). The cost of 12 weeks' participation in such programs (36 sessions) approximates $720.00.

The projected cost of medically directed at-home rehabilitation depends on whether patients purchase or lease the equipment. The following estimates reflect the cost of leasing the exercise cycles and monitoring equipment assuming an average life of 2 years for the equipment. Eighty patients participating for a period of 12 weeks during 1 year would require 20 sets of equipment, 8 to 10% of a physician's time and 30% of a registered nurse's time, trained in cardiac rehabilitation. The cost of 12 weeks' participation approximates $328.00. This cost assumes that the at-home program uses office facilities already dedicated to a similar purpose, such as medically supervised exercise training in YMCA programs.

Costs for 160 Patients Over Two Years

Equipment	Cost ($)
ExerSentry monitors (20 × $110)	2,200
Cardiobeeper monitors (20 × $350)	7,000
Cardiobeeper decodalyzer	1,500
Schwinn XR7 stationary cycles (20 × $250)	5,000
Equipment maintenance ($1,000/year)	2,000
ECG supplies (160 × $5)	800
Telephone costs ($1/call, 12 calls × 160 pts)	1,920
Subtotal	20,420
Cardiology consultation (2 hrs/pt × 160 pts) 8% FTE $12,000 (2 years)	
Registered nurse (at $30,000/year)	
Counseling (3 hrs/pt × 160 = 480 hrs)	5 hrs/wk
Patient phone contact (12 calls × 12 min, each × 160 = 368 hrs)	4 hrs/wk
Records management	
13 hrs/wk = 33% FTE	
= $20,000 (2 yrs)	
Total $52,420	
= $328/patient	

FTE = full-time equivalent.

Effect of Beta-Adrenergic Blockade on the Results of Exercise Testing Related to the Extent of Coronary Artery Disease

STEPHEN W.-C. HO, MBBS, FRACP, MICHAEL J. McCOMISH, MBBS, FRACP, and ROGER R. TAYLOR, MBBS, FRACP

Maximal treadmill testing was carried out in 50 patients with angiographically documented coronary artery disease (CAD) in the presence and absence of β-adrenoceptor blockade. The results were related to the extent of CAD and interpreted relative to the clinical value of exercise testing. Maximal heart rate and systolic blood pressure were significantly lower during treatment with β-blocking drugs. The average exercise duration was 1.3 ± 1.9 minutes greater (± standard deviation), regardless of coronary anatomy. Of the 20 subjects with 3-vessel or left main CAD (severe CAD), 8 patients completed 3 stages (9 minutes) of exercise during treatment; only 4 did so without treatment. Angina was significantly more often the limiting symptom with severe CAD, and this association was abolished by β blockade; 1 of 20 with severe CAD completed 3 stages of exercise and was not limited by angina without β-blocking treatment, whereas 7 had these features during β-blockade therapy. Maximal ST-segment depression was not related to the extent of CAD with or without therapy. Beta blockade suppressed the occurrence of ST depression, or delayed its appearance by an average of 2.0 ± 2.3 minutes and reduced its severity by 0.5 ± 0.9 mm. All tests in which ST depression was completely suppressed were associated with inadequate heart rate response, regarded as diagnostically inconclusive rather than negative. However, during β-blocking treatment, 14 tests (28%) were inconclusive, which, in routine practice, would have necessitated repeat testing. It is concluded that β blockade significantly obscures the diagnostic interpretation of exercise testing and impairs the ability to select subjects likely to have extensive CAD. **(Am J Cardiol 1985;55:258–262)**

The usefulness and limitations of exercise testing are well documented in the diagnosis of myocardial ischemia,[1,2] in predicting the extent of atherosclerotic coronary artery disease (CAD)[2–6] and in selecting high- and low-risk patient groups with CAD.[7–13] Beta-adrenoceptor blocking drugs can delay the onset of angina[14–20] and reduce or delay exercise-induced ST-segment changes,[15,16,21–23] and consequently, many physicians avoid prescribing them before assessing patients by exercise testing. However, some physicians are reluctant to stop therapy in referred patients because of a possible rebound effect.[24] The need to stop therapy for diagnostic testing has been questioned; some believe that the sensitivity of testing, reflected by ST-segment changes, is not impaired.[23] Further, exercise testing is being used increasingly to select for angiography those more likely to have extensive CAD and those with a worse prognosis who may benefit from surgery.[25,26] The purpose of this study was to determine if β-blocker therapy obscures the selection of patients with extensive CAD, to examine how this therapy affects the numerous variables assessed at exercise testing, and to determine if its effects vary with the extent of CAD.

Methods

Patients with angina referred to coronary angiography to evaluate the possibility of surgery were exercised during treatment with β-blocking drugs and without such treatment. Subjects in stable sinus rhythm at rest in whom at least 1 major coronary artery had a 50% reduction in average luminal diameter were included. Some subjects were already receiving treatment and were included in the study if they were receiving metoprolol, 100 mg or atenolol, 50 mg twice daily, propranolol, 40 mg 3 times daily, pindolol 5 mg 4 times daily, or a regimen that produced 20% decrease in heart rate at rest compared with the period without treatment. Exclusion criteria were myocardial infarction within 6 weeks, previous coronary artery bypass surgery or angioplasty, valvular heart

disease, severe hypertension, congestive heart failure, concurrent therapy with digitalis or calcium channel–blocking drugs or electrocardiographic changes at rest (ST-segment depression or bundle branch block) that interfered with test interpretation.

Fifty subjects (47 men, 3 women), aged 33 to 70 years (mean 54 ± 9 [± standard deviation]) were studied, with and without treatment with metoprolol (32 subjects), propranolol (12), atenolol (5), or pindolol (1). The only other drugs being taken were mexiletine, quinidine bisulphate and prazosin each in 1 subject, a thiazide diuretic in 2 and isosorbide nitrate. With the exception of the β-blocking drug, treatment remained unchanged between the 2 exercise tests.

Symptom-limited graded treadmill testing was performed according to the Bruce protocol,[1] commencing in stage 1, at least 2 hours after food, and without knowledge of the coronary angiographic findings. In 25 subjects an exercise test was performed first during β-blocking therapy and a second test after such treatment had been withheld for 48 to 72 hours. The reverse sequence applied to the other 25 patients. Maximal tolerated exercise was undertaken to an endpoint of increasing angina, exhaustion, dyspnea, or, in 1 subject, ventricular tachycardia. A decrease in systolic blood pressure, seen in 3 subjects, did not constitute an endpoint. Heart rate and leads V_5 and modified II of the electrocardiogram were monitored and were recorded (Avionics equipment) at the onset of ST-segment changes and of chest pain, at the end of each stage, at the termination of the test and thereafter at 1-minute intervals until return of the heart rate to 90 beats/min or until disappearance of exercise-induced electrocardiographic changes. Cuff measurements of blood pressure were made at the end of each stage.

The electrocardiographic tracings were analyzed independently by another observer. ST-segment changes were classified according to the criteria proposed by Goldschlager et al[3]: type 1A—at least 1 mm of J-point depression with a downsloping ST segment; type 1B—at least 1 mm of J depression with a horizontal ST segment; type 2—upsloping ST segment that remained depressed at least 1.5 mm at 80 ms after the J point. If less, or no, ST-segment change occurred, the test was defined as negative if the target heart rate—90% of the predicted maximal rate—had been attained but as inconclusive if the target heart rate was not reached.

The results of selective coronary angiography and left ventriculography were analyzed by a third observer without knowledge of the patients' clinical or exercise data. Narrowing of the average luminal diameter of a coronary vessel in multiple views of 50% of more was considered significant. The extent of obstructive disease was characterized as 1-, 2- or 3-vessel, with or without left main (LM) disease, and was also assessed according to the system of Brandt et al.[27] This takes account of the severity of coronary obstructions and the amount of myocardium supplied by obstructed arteries in order to obtain a myocardial score. In the 48 subjects in whom left ventriculography was performed, left ventricular (LV) function was assessed visually and graded subjectively into 2 groups, normal or mildly depressed and moderately or severely depressed.

Group mean results were compared by the Student t test and differences with and without β-blocking therapy were compared using a Student t test for paired data. Comparisons of proportions in different groups were tested by chi-square analysis applying the Yates correction.

Results

One-vessel CAD was present in 14 subjects; the disease involved the left anterior descending coronary artery (LAD) in 8, left circumflex artery in 3 and the right coronary artery in 3 patients. Two-vessel CAD was present in 16 subjects, 4 of whom had proximal LAD involvement. Fifteen patients had 3-vessel CAD; 5 had LM obstruction, 4 of whom had proximal LAD obstruction and 1 of whom had 3-vessel CAD (4 of the 5 had exercise testing before the demonstration of LM obstruction). LV function was normal or mildly depressed in 38 and moderately or severely depressed in 10.

Maximal heart rate and blood pressure: The maximal heart rate with exercise averaged 141 ± 22 beats/min in the absence of β blockade and 113 ± 18 beats/min with β blockade ($p < 0.001$). The rate achieved was not related to the extent of CAD; without β blockade the average heart rate in those with LM CAD was 138 beats/min and in the others it was 141 beats/min. Peak systolic blood pressure attained was 19 ± 21 mm Hg less during β-blocker therapy ($p < 0.001$).

Duration of exercise: The average exercise duration in the 50 subjects was 7.3 ± 2.9 minutes without β-blocking treatment and 8.6 ± 2.6 minutes with β blockade. The 5 subjects with LM CAD had a significantly lower exercise duration than the remainder only when untreated (Fig. 1). Otherwise, those with 1-, 2- and 3-vessel CAD did not have different levels of exercise tolerance. Higher myocardial score tended to be associated with shorter duration of exercise, but had a weak relationship both with and without therapy ($r = -0.24$ and -0.26, respectively, $0.05 < p < 0.1$).

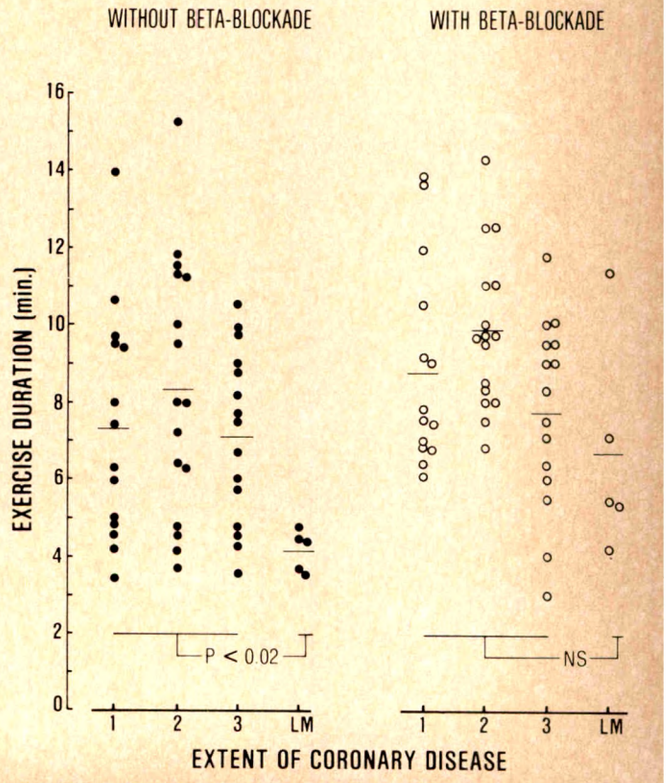

FIGURE 1. Duration of maximal exercise related to the extent of coronary disease. The duration was significantly less in those with left main (LM) disease only in the absence of β blockade. NS = not significant.

Exercise duration averaged 1.3 ± 1.9 minutes more with β blockade than without ($p < 0.001$). The difference was not related to coronary anatomy (Fig. 2), myocardial score or LV function. The difference in exercise duration between the 2 tests was, however, related to the limiting symptom in the absence of β-blocking drug therapy. Beta blockade actually decreased exercise tolerance in 9 of 19 patients limited by fatigue/breathlessness, compared with only 5 of 30 limited by angina ($p < 0.05$).

Four subjects with 3-vessel or LM CAD (severe CAD) completed stage 3 of the Bruce protocol when exercised without β-blocker therapy, whereas with β-blocker therapy, 5 others in addition to 3 of these 4 completed stage 3.

Occurrence of angina and angina as the limiting symptom: During exercise testing without β-blocking treatment, 11 subjects had no angina and angina did not develop when they received therapy. Of the 39 patients in whom angina developed in the absence of β-blocking treatment, 9 did not do so with therapy, and the time of onset of angina was significantly delayed in the other 30, averaging 6.8 ± 2.3 minutes during therapy and 5.7 ± 2.3 minutes without therapy ($p < 0.01$).

In the absence of β-blocking drug treatment, 30 subjects were limited by angina and 20 were not (19 limited by exhaustion/dyspnea and 1 patient by ventricular tachycardia), while during therapy 17 were limited by angina and 33 by exhaustion/dyspnea ($p < 0.02$). Without β-blocking treatment the nature of the limiting symptom was related to the extent of CAD and to the myocardial score. Severe CAD was present in 17 of 30 patients limited by angina, but in only 3 of the 20 patients not limited by angina ($p < 0.01$) (Fig. 3, top).

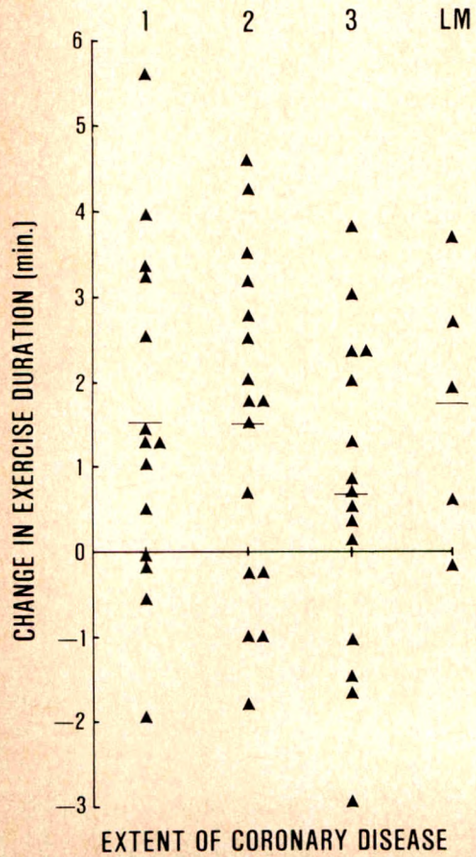

FIGURE 2. The change in duration of exercise with β blockade bears no relation to the extent of coronary disease. LM = left main.

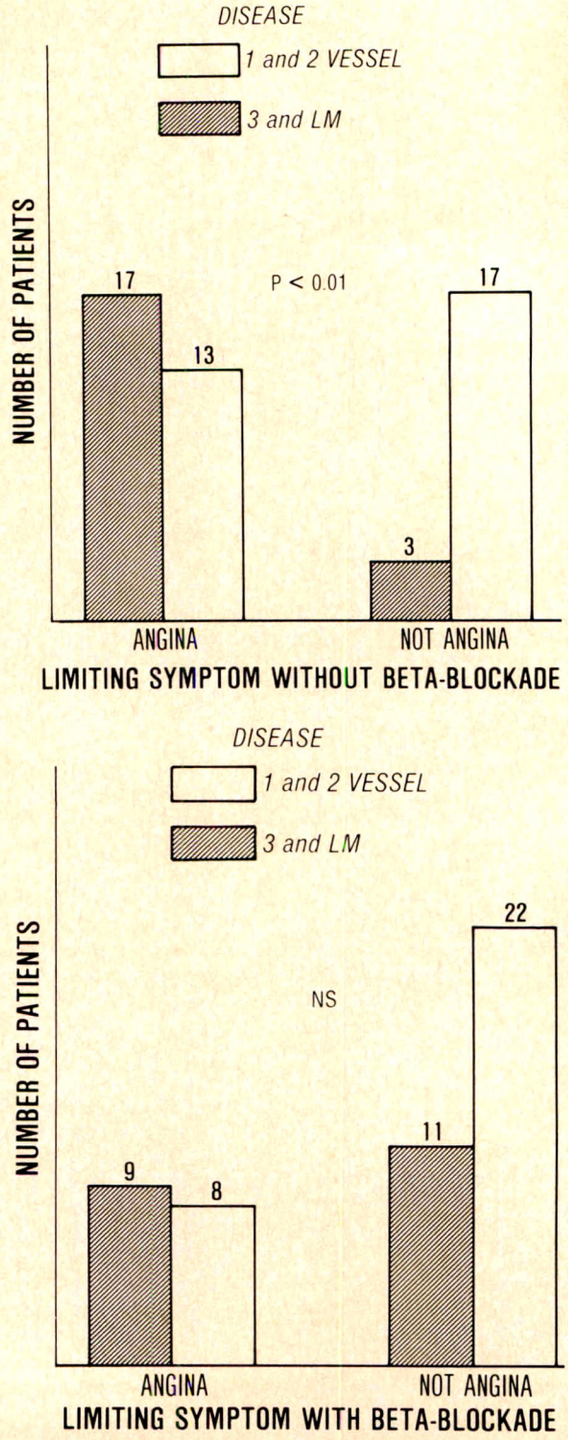

FIGURE 3. When angina was not the limiting symptom, 3-vessel or left main (LM) disease was uncommon in the absence of β blockade (**top**), but this was not so in the presence of β blockade (**bottom**). NS = not significant.

The myocardial score was 8.0 ± 2.4 in the patients limited by angina and 5.7 ± 2.5 in those not limited by angina ($p < 0.01$).

The relation between the limiting symptom of angina and the severity of CAD was abolished by treatment with β-blocking drugs (Fig. 3, bottom). Four of the 5 patients with LM CAD were limited by angina without treatment but only 1 patient was so limited with treatment. The change in the limiting symptom produced by β-blocking treatment was not related to LV function, and limitation by exhaustion/dyspnea was not associated with poor LV function assessed at angiography. In fact, 8 of the 10 subjects with moderate or severe depression of LV function were limited by angina when not receiving β-blocking therapy.

ST-segment changes: In the absence of β blockade, 3 subjects had negative test responses in terms of ST-segment depression, and 8 had inconclusive results. The inconclusive test results included only 1 subject with 3-vessel CAD; all others with severe CAD had ST-segment depression. Those with ST changes also had higher myocardial scores than those without (7.8 ± 2.5 vs 4.6 ± 1.8, $p < 0.001$). However, among those with ST depression, neither the magnitude nor the grading related to the extent of CAD; those with severe and mild disease had similar average ST depression, and no single level of ST depression, such as 2 or 3 mm, was associated with a greater proportion of patients with severe CAD.

Figure 4 shows how β-blocker treatment affected ST-segment grading. In 24 subjects the ST grade was unchanged between tests: 13 with grade 1A ST changes, 2 with grade 1B, and 2 with grade 2; in 1 patient the results were negative and in 6 the results were inconclusive on both tests. The grade was decreased by β-blocking treatment in 19 patients and it was increased in 7 patients; the changes were unrelated to coronary anatomy, myocardial score or LV function. Six patients with positive test responses without treatment had inconclusive responses during treatment; 1 of these patients had 3-vessel and 1 LM CAD. However, no test response changed to negative. Fourteen patients had inconclusive test responses during treatment; 2 of these patients had 3-vessel and 1 had LM CAD.

The onset of ST depression in those in whom it occurred in both tests was delayed an average of 2.0 ± 2.3 min ($p < 0.001$), without relation to the extent of CAD. Beta blockade decreased the maximal ST depression by an average of 0.5 ± 0.9 mm ($p < 0.01$), although in 8 patients an increase in ST depression occurred that was associated with a longer duration of exercise. The magnitude of the change was not related to the extent of CAD, but had a direct linear relation to the absolute magnitude of ST depression without β blockade ($p < 0.001$); that is, a proportionate reduction in ST depression tended to be produced.

Discussion

The increase in exercise tolerance with β-blocking treatment usually described in patients with CAD is, in fact, a delayed onset of angina in a submaximal test.[14,15,17–20] Our results agree that angina may be delayed or abolished.[14,19,22] The duration of maximal tolerated exercise increased, agreeing with some study results[16] but not with others.[28] Maximal exercise tolerance undoubtedly may decrease in the normal subject.[29] Our conclusions are relevant to the exercise testing of subjects with probable or established CAD, although the detailed results pertain to the group studied.

The object was to determine how β blockade influences exercise test variables that have diagnostic or prognostic value. The duration of maximal exercise is one of the best guides to prognosis in patients with CAD.[2,8–13] Those with a good exercise tolerance have a good prognosis, even among subjects with a markedly positive test in terms of ST-segment change[10,11] or in patients with 3-vessel CAD.[13] Ability to complete stage 3 of the Bruce protocol is associated with a good prognosis and a low incidence of LM or 3-vessel CAD.[2,8–13] In our study, in the absence of β blockade, 4 of 20 subjects with 3-vessel or LM CAD completed stage 3 of the Bruce protocol; during β-blocking treatment, 8 did so. Of course, we did not address the possibility that the improvement in exercise tolerance with β-blocking drug treatment may be accompanied by an appropriate improvement in prognosis.

The association of angina as the limiting symptom with the extent of CAD may explain the additional prognostic significance some have found associated with the occurrence of angina during exercise testing, even in those with known CAD.[2,7] Beta-blocking drug treatment tended to convert the limiting symptom from angina, especially in those with extensive CAD. Without β-blocking treatment, all but 3 of the 20 with severe CAD were limited by angina but during treatment only 9 were so limited. The absence of angina as the limiting symptom, coupled with the ability to complete 9 minutes of exercise, was seen in only 1 patient in this category without treatment, but both of these features were present in 7 during treatment. Hence, consideration of

1B	5	2	4	0	1
2	3	3	2	0	0
N	0	0	0	1	0
I	2	3	1	2	6

FIGURE 4. Classification of ST-segment depression with (on) and without (off) β blockade. The numbers of subjects with a given ST grade without β blockade are read in the **vertical columns** and the numbers on β-blockade in the **horizontal columns.** I = inconclusive; N = negative. See text for description.

the limiting symptom and the duration of exercise together would allow reasonable exclusion of severe CAD only in the absence of β-blocking drug treatment.

Disagreement exists concerning the effect of β blockade on exercise-induced ST-segment changes. The consensus is that the onset of ST-segment depression is delayed,[15,21] as we found. However, some investigators have found the ST-segment depression occurring during testing is decreased[15,16,22,23]; others have found that it did not change.[18,21] Exercise in some of these studies was submaximal,[15,16,18,22] so that the reported ST-segment depression was that occurring at the onset of angina or corresponding endpoint. How this is affected is not really germane to maximal exercise testing, for either diagnostic or prognostic purposes. We found that ST-segment depression at maximal exercise decreased, consistent with some observations[16,23,30] but not others.[21] Recent studies support the prognostic value of ST-segment depression,[13] which is influenced by β blockade, although the predictive value of marked changes per se may be less than formerly believed.[10,11] We found no relation between the extent of ST depression and the extent of CAD even in the absence of β blockade.

From the diagnostic viewpoint, in terms of ST-segment change, some have considered that β blockade reduces the incidence of false-positive test responses without increasing the incidence of false-negative responses.[23] Although none of our positive test results were converted to strictly negative results, 6 were converted to inconclusive tests that would have been classified as negative by Marcomichelakis et al.[23] The idea of a target heart rate during β-blocker therapy may be questioned but, in practice, the absence of ST changes can hardly be regarded as a negative response when heart rate is not adequately raised. When these additional 6 inconclusive results are added to the others, there were a total of 14 inconclusive tests during treatment. Hence, if our subjects had undergone exercise testing for diagnostic purposes while receiving β-blocker therapy, 28% of the tests should have been repeated without treatment.

Kardash et al[20] described a different approach to analyzing ST-segment changes by relating the progressive ST changes throughout exercise to concurrent heart rate changes, obtaining an ST/HR regression. Excellent agreement was found between the results and the extent of CAD, even in the presence of β blockade.[20] Kardash et al monitored 13 leads, but the analysis is also critically dependent upon minute fractional measurement of ST depression, the practicality of which is questionable.

Early Exercise Training in Patients Older than Age 65 Years Compared with that in Younger Patients After Acute Myocardial Infarction or Coronary Artery Bypass Grafting

MARK A. WILLIAMS, PhD, CARL M. MARESH, PhD, DENNIS J. ESTERBROOKS, MD, JAMES J. HARBRECHT, MD, and MICHAEL H. SKETCH, MD

To evaluate potential benefits that elderly cardiac patients might gain from early exercise programs, 361 such patients were studied: group I—60 patients aged 44 years or younger; group II—114 patients aged 45 to 54 years; group III—111 patients aged 55 to 64 years; and group IV—76 elderly patients aged 65 years or older. All patients participated in a 12-week exercise program within 6 weeks of acute myocardial infarction or coronary artery bypass grafting. All patients performed symptom-limited exercise tests before and after completion of the exercise program. Between tests, elderly patients manifested significant differences in body weight (76.9 to 75.2 kg), percent body fat (22.3 to 20.8 kg), heart rate at rest (77 to 68 beats/min), maximal heart rate (126 to 138 beats/min), maximal METs (5.3 to 8.1), submaximal average double product (17,305 to 14,071), and submaximal average rating of perceived exertion (12 to 10 [$p < 0.05$]). Magnitudes of change were similar among groups, although the elderly patient group had a significantly lower absolute physical work capacity at testing after training than the other 3 groups ($p < 0.05$). In the 25 elderly patients who received β-blocking drugs, METs increased from 5.1 to 7.8 ($p < 0.05$). In the remaining 51 elderly patients not receiving β-blocking drugs, METs increased from 5.4 to 8.2 ($p < 0.05$). The magnitude of increase in patients who received β-blocking drugs was not significantly different from that in patients not receiving β-blocking drugs. Results suggest that benefits of early exercise programs seen in young cardiac patients may also be expected in elderly cardiac patients. (Am J Cardiol 1985;55:263–266)

The benefits of exercise training as part of the rehabilitation of cardiac patients have been described by previous investigators. Improvement in the hemodynamic responses to exercise,[1–3] physical work capacity[4–6] and cardiac function[7–9] have been described. Potential improvements in morbidity, mortality[10–12] and pyschologic responses to heart disease[13,14] have also been described. Typically, the subjects who participated in these studies had had acute myocardial infarction (AMI) or had undergone coronary artery bypass grafting (CABG) from the ages of 45 to 65 years. To our knowledge, the benefits of exercise training in elderly cardiac patients have not been described. Therefore, in this study, we evaluated the results achieved from exercise training in 76 elderly cardiac patients and compared the data with those obtained from 285 subgrouped, younger cardiac patients.

Methods

To provide adequate patient numbers for evaluation, a collaborative investigation that involved the outpatient cardiac rehabilitation exercise programs of Creighton University/St. Joseph Hospital, Omaha, Nebraska, and St. Luke's Hospital, Kansas City, Missouri, was undertaken. Standard criteria for the exclusion of patients from cardiac exercise training were used.[15] Both programs had similar protocols of patient evaluation and exercise training. Three hundred sixty-one men, 166 after myocardial infarction and 195 after CABG, were studied. Ninety-three of the 195 CABG patients (48%) had histories of myocardial infarction. All patients began the exercise training program within 6 weeks (mean 4.5) of AMI or CABG. Patients were instructed to continue taking all prescribed medications before testing and during the exercise program. Subjects were classified into 4 groups according to age. Group I patients (n = 60) were 44 years or younger (mean 40 ± 4); group II patients (n = 114) were 45 to 54 years (mean 50 ± 3); group III patients (n = 111) were 55

TABLE I Results of the Evaluation of Elderly Patients Before and After Training (Group IV, Mean Age 70.2 ± 3.2 Years)

	Before Training	After Training

to 64 years (mean 59 ± 3); and group IV patients (n = 76) were 65 to 82 years (mean 70 ± 3).

Before and after the exercise training program, all patients received an evaluation that included a continuous, multistage treadmill test performed until onset of contraindicating signs, symptoms or fatigue (72% fatigue, 11% complex ventricular arrhythmias, 10% angina and 7% ST-segment depression). The protocol allowed for increases in work of 1 MET per stage.[16] Treadmills were regularly calibrated and patients were instructed not to hold onto the handrails of the treadmill. Standard 12-lead electrocardiograms were obtained from each patient at rest in both the supine and standing positions, during the last 15 seconds of each exercise stage, immediately on cessation of exercise while standing, and at minutes 1 through 6 of supine or seated recovery. Data collected from the exercise tests included heart rate (HR) and blood pressure (BP) at rest, exercise HR and BP, exercise HR-BP product, estimation of the patient's physical work capacity in METs and ratings of perceived exertion.[17] The average values of actual HB-BP products and ratings of perceived exertion were calculated from comparable submaximal treadmill stages.[18]

The percentage of body fat was estimated using a skinfold measurement technique.[19] Pulmonary function studies (vital capacity and forced expiratory volume in 1 second) were obtained in 34 of the 76 elderly patients.

Before participating in the study protocol, each patient signed an informed consent for participation. After initial evaluation, each patient entered a 12-week exercise program that consisted of 40 minutes of circuit-station training using alternating arm and leg exercise 3 days/week. During the exercise sessions, the electrocardiograms of all patients were continuously monitored using a single bipolar lead, hardwire or telemetry, central station monitoring system. Hard copy printouts were periodically recorded. The intensity of exercise training resulted in HR that ranged between 70 and 85% of the maximal HR attained during symptom-limited exercise testing. Exercise heart rates were maintained within 5 beats of each patient's HR prescription.

Statistical analysis was accomplished using an IBM systems 4341 computer and programs from the statistical package for social sciences (SPSS).[20] Data were analyzed using a Student

TABLE II Results of Exercise Tests Before and After Training in Elderly Patients

	Before Training	After Training
After AMI (n = 41)		
Physical work capacity (METs)	5.4 ± 1.3	8.0 ± 1.4*
Average HR × BP × 10^{-2} (submaximal)	168 ± 43	135 ± 33*
Average RPE (submaximal)	13 ± 2	11 ± 2*
After CABG (n = 35)		
Physical work capacity (METs)	5.1 ± 1.3	8.1 ± 1.8*
Average HR × BP × 10^{-2} (submaximal)	179 ± 44	148 ± 36*
Average RPE (submaximal)	12 ± 2	10 ± 2*

* $p < 0.05$.
AMI = acute myocardial infarction; CABG = coronary artery bypass grafting; other abbreviations as in Table I.

t test for both correlated means and noncorrelated means. A p value of less than 0.05 was considered significant when comparing groups of means.

Results

Overall program attendance was 85% (range 44 to 100%). Attendance among the elderly patient group was 90%. No patient experienced an untoward event during either exercise testing or training.

The results of the evaluations in the elderly patients and selected subgroups before and after training are listed in Tables I to III. After training, as a group, elderly patients showed significant decreases in body weight and percentage of body fat ($p < 0.05$). Their mean HR at rest significantly decreased during the training period ($p < 0.05$). The BP at rest did not change significantly. Subsequent to training, vital capacity was unchanged. However, forced expiratory volume in 1 second significantly increased ($p < 0.05$).

Comparisons of the maximal and submaximal exercise test variables before and after training (Table I) showed significant differences ($p < 0.05$). Maximal HR, systolic BP, HR-BP product and physical work capacity were significantly increased after training. Submaximal exercise average HR-BP and average ratings of perceived exertion were significantly lower after training. Within the elderly group there was a nonsignificant negative correlation between age and improved physical work capacity ($r = -0.11$).

The results of exercise tests before and after training in AMI and CABG patients are listed in Table II. The differences before and after training were significant in both AMI and CABG patients ($p < 0.05$). However, the changes were not significant between AMI and CABG patients even though CABG patients had a greater percent increase (48 vs 59%) in physical work capacity than AMI patients.

Table III lists the results of exercise testing before and after training in the elderly patients when subgrouped for use of β-blocking medications. There were significant differences before and after training in both groups ($p < 0.05$). Both groups had greater physical work capacities, lower submaximal average HR-BP product, and lower submaximal average ratings of perceived exertion after training. A comparison of the 2 groups for

TABLE III Test Results Before and After Training in Elderly Patients

	Before Training	After Training
β blockade (n = 25)		
Physical work capacity (METs)	5.1 ± 1.5	7.8 ± 1.4*
Average HR × BP × 10^{-2} (submaximal)	155 ± 38	125 ±28*
Average RPE (submaximal)	13 ± 2	11 ± 2*
No β blockade (n = 51)		
Physical work capacity (METs)	5.4 ± 1.2	8.2 ± 1.6*
Average HR × BP × 10^{-2} (submaximal)	182 ± 44†	149 ± 35*,†
Average RPE (submaximal)	12 ± 2	10 ± 2*

* $p < 0.05$.
† Significantly different ($p < 0.05$) from β-blockade group.
Abbreviations as in Table I.

differences in magnitudes of change revealed no significant difference, although the group without β-blocking therapy had a slightly greater increase in physical work capacity than the group with β-blocking therapy.

There was no significant difference between the elderly group and any other group with respect to the percentage of patients who received β-blocking medication ($p < 0.05$) (group I—23%, group II—25%, group III—38%, and group IV—33%). Therefore, these patients were included for the between-group comparisons. Table IV lists the results of exercise testing before and after training in each of the 4 age groups. All 4 groups evidenced significantly different pre- and posttraining variables ($p < 0.05$). After training, physical work capacity was greater, and submaximal average HR-BP product and ratings of perceived exertion were lower in all 4 groups. With the exception of physical work capacity in the youngest (group I) versus that in the elderly (group IV) patients, there were no significant differences in magnitudes of change between groups, although the elderly patient group had a significantly lower absolute physical work capacity at testing after training than the other 3 groups ($p < 0.05$).

Discussion

The aging process has been demonstrated to alter cardiorespiratory function with resultant diminished functional capacity.[21–23] In healthy, elderly subjects, improvement in endurance and functional capacity can be achieved with exercise training.[24,25] The present study suggests that this finding is also true in elderly persons with ischemic heart disease and that the improvement is similar to that manifested by younger patients. After training, our elderly cardiac patients demonstrated a significant increase in maximal exercise tolerance, a decrease in myocardial work (HR-BP product) at submaximal workloads, and a decrease in perception of effort at standardized work intensities. Higher maximal HR-BP product values after training suggest that the increased exercise capacity of our elderly patients was due to their ability to perform at higher myocardial oxygen demand levels.[26,27]

In 46 male cardiac patients (aged 37 to 68 years [mean age 54]) who had no exercise training, Savin et al[28] found a 25% increased peak oxygen uptake and a 10% decrease in submaximal HR-BP product during the initial weeks after recovery from AMI. Hence, it is possible that some of the improvement we noted after training was a result of "spontaneous improvement" unrelated to exercise training. However, in this study, in patients of similar age (40 to 64 years [mean 53]), there was an increase in physical work capacity of 48% and a decrease in submaximal HR-BP product of 17%. Elderly patients showed a 53% increase in physical work capacity and an 18% decrease in submaximal average HR-BP product. Although Savin et al[28] used direct measurement of oxygen uptake and this study used estimated oxygen uptake, the magnitudes of change in our patients were considerably greater than those reported by Savin, suggesting that the improvements were more than what would be expected from "spontaneous improvement" alone.

Cardiac patients have reported increases in self-confidence and less fear of physical exertion after training both with and without improvements in peripheral or cardiac measurements.[29–31] Thus, although the observed improvements shown in this study may represent training effects derived from peripheral and cardiac function adaptations, they may also have resulted, at least in part, from the patients' willingness to push themselves harder toward maximal physical work capacities after the program. The elderly patient group did show a significant increase in maximal HR from exercise tests before and after training (126 to 138 beats/min). Thus, the evaluation of standardized submaximal parameters as described previously is an important tool to measure training effects in these patients. However, no significant differences were seen in

TABLE IV Exercise Test Results Before and After Training in All Four Age Groups

	Before Training	After Training
Group I (mean age 40 ± 4 yrs)		
Physical work capacity (METs)	6.3 ± 1.6	9.8 ± 1.6*,†
Average HR × BP × 10^{-2} (submaximal)	170 ± 33	143 ± 33*
Average RPE (submaximal)	12 ± 2	9 ± 2*,†
Group II (mean age 50 ± 3 yrs)

maximal ratings of perceived exertion between tests before and after training.

It is concluded that elderly male, cardiac patients benefit from participation in early exercise programs through enhanced functional capacity and improved psychologic responses to exertion. Furthermore, as a result of decreased submaximal myocardial oxygen demand, they may be less symptomatic during their daily routines, which should enhance the quality of their lives. Finally, elderly patients appear to be at no greater risk from participation in exercise programs than younger patients and should not be excluded from early exercise rehabilitation exercise programs simply on the basis of age.

Early Positive Exercise Test and Extensive Coronary Disease: Effect of Antianginal Therapy

JHULAN MUKHARJI, MD, MARK KREMERS, MD, KIRK LIPSCOMB, MD, and C. GUNNAR BLOMQVIST, MD

The effect of antianginal therapy on the incidence of an early positive exercise response as a screening tool for 3-vessel and left main (LM) coronary artery disease (CAD) was examined. Fifty-seven men with stable angina pectoris underwent bicycle ergometry before and after long-acting nitrate or calcium antagonist therapy was instituted. An early positive response was defined as signs of myocardial ischemia at low levels of myocardial and total body workload (corresponding to a workload of less than 300 kpm/min). Thirty-nine patients (68%) had an early positive response before therapy, compared with 14 (24%) after therapy. Of 24 patients undergoing coronary angiography, 12 had 3-vessel CAD (including 2 with LM), 5 had 2-vessel CAD, 6 had 1-vessel CAD and 1 patient had no CAD. The sensitivity and specificity of an early positive response in predicting 3-vessel/LM CAD changed from 92% and 58% before to 42% and 75% after therapy. The positive and negative predictive values changed from 69% and 88% before to 63% and 63% after therapy. It is concluded that antianginal therapy reduces the value of an exercise test as a screening tool for 3-vessel/LM CAD.

(Am J Cardiol 1985;55:267–270)

Exercise testing is often used as a prognostic tool in patients with known coronary artery disease (CAD). Early positive tests, defined as signs of myocardial ischemia at low levels of myocardial and total body workload, are associated with an increased likelihood of 3-vessel or left main (LM) CAD and a poor prognosis.[1–4] Because surgery may improve prognosis in subsets of these patients,[5] an early positive exercise test is frequently used to select patients for cardiac catheterization. The effect of antianginal drug therapy on the occurrence and accuracy of an early positive exercise test is not known. Therefore, the present study was performed to assess the incidence and implications of an early positive response in patients who underwent serial exercise testing before and after antianginal therapy, and to assess the effect of antianginal therapy on the ability of an early positive response to predict coronary artery anatomy.

Methods

The study group consisted of 61 men, aged 57 ± 7 years (mean ± standard deviation), who participated in study protocols that evaluated calcium antagonists (bepridil and lidoflazine) and a long-acting nitrate (Nitro-Bid®). Entry criteria for the study included typical stable angina pectoris with more than 5 episodes of chest pain per week for more than 6 months preceding enrollment. In addition, an ischemic ST-segment response (more than 1 mm of ST-segment depression) during previous exercise testing was required. All antianginal drugs except sublingual nitroglycerin were discontinued for more than 4 weeks before obtaining a baseline exercise study. Multistage upright bicycle exercise was performed on a Monark bicycle ergometer beginning at a workload of 150 kpm/min with increments of 150 kpm/3 min. Orthogonal Frank leads X, Y and Z were monitored continuously throughout the exercise test. Permanent electrocardiographic recordings at 25 mm/s were obtained in the final minute of each stage of exercise. Blood pressure (BP) was measured at rest, at the end of each stage, at exercise termination, and every 3 minutes for 6 minutes after termination. End points of the exercise test in this study included downsloping or horizontal ST depression more than 1 mm from the baseline, measured 80 ms after the J point in any lead, or incapacitating symptoms, including angina, dyspnea, weakness and fatigue. No patient was taking digitalis glycosides and no patient had other signs or symptoms that would constitute a reason to terminate the test.

An early positive test response was defined as the occurrence of significant ST deviation within the first 6 minutes of

TABLE I Comparison Between Total Study Group and Coronary Arteriography Group

	Total Study Group (%)	Coronary Arteriography Group (%)
No. of pts	57	24
Age	57 ± 7	56 ± 8
Risk factors	1.4	1.3
Baseline early +	39 (68) *	16 (66) †
After therapy early +	14 (25) *	8 (33) †

* $p < 0.01$; † $p < 0.05$.
Risk = diabetes mellitus, hypertension, smoking, prior myocardial infarction; + = positive response.

exercise (stage 2, corresponding to a workload of less than 300 kpm) or the failure to complete stage 2 and achieve at least 75% of age-predicted maximal heart rate (HR) in the absence of significant ST deviation.[1,2] After the baseline study, antianginal treatment was begun with long-acting nitrates (19 patients) and calcium antagonists (38 patients). The dosage of drugs was as follows: bepridil, 200 to 400 mg once daily (to tolerance); lidoflazine, 120 mg 3 times daily; and nitrobid, 6.5 mg twice daily. Exercise testing was subsequently repeated at a mean interval of 4 ± 3 months while patients continued to receive antianginal therapy. Coronary angiography was performed in 24 patients. Significant stenosis was defined as more than 50% luminal narrowing and the extent of disease was classified as 0-, 1-, 2- and 3-vessel, or LM CAD. Decisions regarding cardiac catheterization were made at the discretion of physicians involved in the management of individual patients.

Statistical analysis: Values are expressed as mean ± standard deviation. McNemar's test was used to assess the change in status (yes or no for an early positive response) from baseline to after therapy in the entire group and separately in the group that underwent angiography. A Student *t* test for paired observations was used to compare the change from before to after therapy in HR, HR-BP product, BP and exercise workload in each of 4 groups—early and before therapy, nonearly and before therapy, early and after therapy, and nonearly and after therapy.

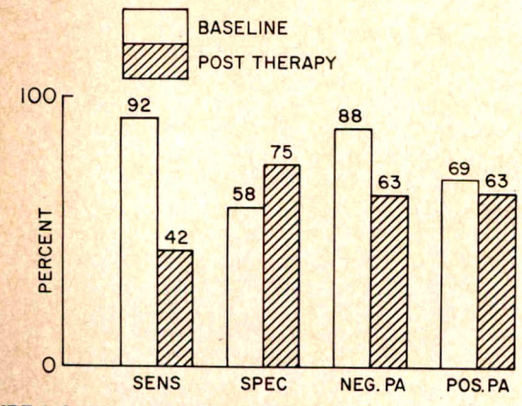

FIGURE 1. Sensitivity (SENS), specificity (SPEC) and predictive accuracy (PA) of an early positive exercise response for the detection of 3-vessel and left main coronary artery disease. Comparison between exercise tests performed before and after antianginal therapy in patients undergoing coronary arteriography. Numerical values indicate percentages. NEG. = negative; POS. = positive.

Analysis of variance with 1 repeated measure (before and after therapy) and 1 independent (or grouping) factor was used to compare the effect of therapy for BP, HR, HR-BP product and exercise workload in subjects who did vs those who did not undergo catheterization.

Results

In 1 patient unstable angina developed, and coronary artery bypass surgery was performed. Three patients were lost to follow-up before the second exercise test. Hence, complete data are available in 57 patients who had satisfied entry criteria for the study, including electrocardiographic evidence of myocardial ischemia during a previous exercise test. At the baseline exercise study, 39 patients (68%) had an early positive test response (Table I). Of these, 37 patients had 1 mm or more of ST-segment depression and 2 were unable to achieve more than 75% of maximal predicted HR and had a total exercise duration of less than 6 minutes (corresponding to a total body workload of less than 300 kpm). After initiation of antianginal therapy, only 14 patients (25%) had an early positive response ($p < 0.01$), all of whom had 1 mm or more of ST-segment depression in less than 6 minutes. Thirteen of these 14 patients had early positive responses at baseline as well. Baseline clinical characteristics were comparable within patient groups (Table II). No statistical differences were noted in baseline peak HR, peak systolic BP and HR-BP product when data were analyzed in patients grouped according to early positive responses before and after antianginal therapy (Table III). The overall peak workload achieved increased from a mean value of 302 ± 130 to 408 ± 123 kpm with therapy ($p < 0.001$). Similar significant increases were also noted individually in both patient groups (Table III). Antianginal drug treatment caused a 63% reduction in the occurrence of early positive tests. Finally, changes in total body work were compared among patients given various antianginal agents, and no significant differences were noted.

In the subgroup of 24 patients who underwent coronary arteriography, 16 (66%) early positive tests were noted at baseline (Table I). Eight patients (33%) continued to have an early positive test during antianginal therapy ($p < 0.05$). Twelve of the 24 patients (50%) had 3-vessel CAD, 5 (21%) had 2-vessel CAD, 6 (25%) had 1-vessel CAD, and in 1 patient there was no significant CAD by angiography. Two patients had LM CAD in addition to 3-vessel CAD. Before therapy an early positive test had a sensitivity of 92% (11 of 12) and a specificity of 58% (7 of 12) in detecting LM or 3-vessel CAD (Fig. 1). Both patients with LM CAD were correctly identified. After therapy, the sensitivity decreased to 42% (5 of 12) and the specificity increased to 75% (9 of 12) (Fig. 1). The predictive accuracy of a positive test for LM or 3-vessel CAD before therapy was 69% (11 of 16) and of a negative test 88% (7 of 8). After treatment these values changed to 63% and 63%, respectively (Fig. 1). Patients who converted from an early positive to a non-early positive test with antianginal therapy included 6 with 3-vessel CAD, including 1 patient with LM CAD. Baseline characteristics and re-

sponse to therapy were comparable in the overall study group and in the group that underwent coronary arteriography (Table I). No significant differences were found between patients with 3-vessel/LM CAD and 0- to 2-vessel CAD in left ventricular ejection fraction, left ventricular end-diastolic pressure, left ventricular mass and incidence of wall motion abnormality.

Discussion

This study addresses the issue of using the exercise test as a screening tool to identify patients with severe CAD, and examines the effect of antianginal therapy on the use of an early positive ischemic response for this purpose. Although an ideal screening test should be highly sensitive and specific, it may be considered adequate if it is highly sensitive and possesses a reasonable degree of specificity and predictive value. Our data suggest that in patients with a high probability of CAD, an early positive exercise test response before the institution of antianginal therapy is a highly sensitive marker of extensive disease; however, antianginal therapy substantially reduces the sensitivity of the early positive response without markedly improving its specificity (Fig. 1).

Several exercise criteria have been used as markers of 3-vessel and LM CAD. These include limited total work capacity, abnormal BP and HR response, severity and duration of ST-segment depression, and early onset of ischemic ST-segment changes.[1–4,6–10] Exercise-induced hypotension in patients without valve dysfunction is a specific but insensitive marker for extensive disease.[6] None of our patients had such a response. Ellestad and Wan[2] and Schneider et al[4] showed that ST-segment change at a reduced workload is a better predictor of severe CAD than the extent of ST depression. Additionally, in our institution[11] and in others, exercise is terminated after the development of more than 1 mm of unequivocal ST-segment deviation from baseline. Greater ST-segment change is therefore infrequently seen. McNeer et al[1] and Ellestad and Wan[2] determined that an abnormal chronotropic response in the absence of β-blocking therapy is significantly associated with severe CAD. Consequently, we used ST-segment depression at a reduced workload and an attenuated chronotropic response with limited total work capacity as markers of extensive CAD.

To our knowledge, no previously published study has assessed the effect of antianginal therapy on the prognostic implications of an early positive exercise test. McNeer et al[1] found no change in the order of importance of prognostic variables when propranolol was considered. Blomqvist et al[12] found that β-blocking drugs did not obscure differences in mean peak workloads among patients grouped according to coronary anatomy. These studies considered differences in mean values among groups and did not report changes in individual responses using patients as their own controls. Nixon et al[13] reported that although propranolol did not affect the frequency of an ischemic response to exercise in groups of patients with LM or 3-vessel CAD, it did abolish differences in peak workload that might be used to distinguish the extent and severity of CAD. Our study supports and extends these findings.

This study has certain limitations, and the results must be interpreted accordingly. First, we examined a select group of men with typical angina pectoris and a high probability of CAD. Extending the results to other patient groups could therefore be misleading. Second, anatomic correlations were available in 24 of the 57 patients and the possibility of selection bias must be considered. However, the exercise variables, response

to therapy and baseline characteristics were similar in the overall study group and in the group undergoing coronary arteriography (Tables I and IV); the distribution of the extent of CAD is similar to findings reported in patients with stable angina pectoris.[14] Therefore, we believe that significant selection bias is not a major concern. Finally, despite its popular usage, the somewhat simplistic 3-vessel classification of coronary anatomy does not completely define prognosis. Hence, our findings cannot be extrapolated to define prognosis completely, which is influenced as well by several other variables. The clinical significance of changes in prognostic exercise variables induced by antianginal therapy is currently unknown. Further studies using large patient populations followed over a long period are required to determine this relation. One may reasonably conclude that conversion from the early positive to the non-early positive response group by antianginal therapy is not an assurance of favorable coronary anatomy, and that exercise testing should ideally be performed without antianginal therapy when screening for severe CAD.

Improved Accuracy of the Exercise Electrocardiogram: Identification of Three-Vessel Coronary Disease in Stable Angina Pectoris by Analysis of Peak Rate-Related Changes in ST Segments

PETER M. OKIN, MD, PAUL KLIGFIELD, MD, OLIVIER AMEISEN, MD, HARVEY L. GOLDBERG, MD, and JEFFREY S. BORER, MD

Exercise electrocardiography has relatively poor specificity and predictive accuracy for 3-vessel coronary artery disease (CAD) when conventional diagnostic criteria are used. However, electrocardiographic evaluation using linear regression analysis of the heart-rate (HR)-related change in ST-segment depression (ST/HR slope) is reported to accurately distinguish patients with from those without CAD, and to accurately separate patients with 1-, 2- and 3-vessel CAD. To assess the applicability of this method and to compare it with conventional interpretation, retrospective evaluation of 50 patients in whom exercise electrocardiography and coronary cineangiography had been performed for suspected CAD was conducted using a modified ST/HR slope analysis limited to leads V_5, V_6 and aVF. Eighteen patients had 3-vessel, 22 had 2-vessel, 6 had 1-vessel and 4 had no CAD. Standard electrocardiographic criteria (1 mm or more of horizontal or downsloping ST depression) identified 3-vessel CAD with a sensitivity of 78%, specificity of 56% and positive predictive value of only 50%. Peak ST/HR slope criteria ($\geq$6.0 μV/beat/min) identified 3-vessel CAD with a sensitivity of 78%, specificity of 97% and positive predictive value of 93%. The overall test accuracy using measured peak ST/HR slope was 90%, compared with 64% for standard ST-depression criteria. In conclusion, analysis of the peak ST/HR slope can greatly improve the diagnostic accuracy of exercise electrocardiography, and further prospective study of this method is indicated.

(Am J Cardiol 1985;55:271–276)

The clinical evaluation of coronary artery disease (CAD) often involves interpretation of the exercise electrocardiogram. However, the accurate identification of patients with and without CAD is limited by poor test sensitivity and specificity,[1–5] and assessment of the severity of CAD among patients with angina pectoris is limited by availability of predictive discriminators.[1–3,5–8] The need for accurate noninvasive identification of 3-vessel and left main CAD is highlighted by studies that demonstrate improved survival with coronary artery bypass surgery in these disease subsets.[9–11]

Evaluation of the exercise electrocardiogram using linear regression analysis of the peak heart rate (HR)–related change in ST-segment depression with exercise has recently been reported to accurately separate patients with no, 1-, 2- and 3-vessel CAD.[12–14] To assess the applicability of this method for the identification of 3-vessel and left main CAD, we evaluated 50 patients in whom exercise electrocardiography and coronary cineangiography were performed for suspected coronary ischemia.

Methods

Patients: Records of 50 consecutive patients with stable angina pectoris who had undergone both exercise electrocardiography and coronary angiography were reviewed. Patients with coexisting valvular heart disease, myocardial infarction within 6 weeks of exercise testing and left bundle branch block were excluded from analysis.

Coronary angiography: Selective coronary cineangiography was performed with multiple views in all patients. The extent of CAD was determined as the percent narrowing of the luminal diameter based on views in multiple planes. Patients

TABLE I Comparison of Patient Characteristics According to Extent of Coronary Artery Disease

Patient Characteristics	0-, 1- and 2-Vessel CAD (n = 32)	3-Vessel CAD (n = 18)	p Value
Age (yr)	50 ± 1.7	57 ± 2.8	<0.05
Duration of ex (stages)	2.6 ± 0.2	1.9 ± 0.2	<0.05
Magnitude of ST depression (mm)	0.9 ± 0.2	2.0 ± 0.3	<0.001
Peak HR (beats/min)	132 ± 5	121 ± 6	NS
Change in HR (beats/min)	60 ± 5	50 ± 4	NS
Peak systolic BP (mm Hg)	152 ± 6	137 ± 7	NS
Change in systolic BP (mm Hg)	31 ± 5	23 ± 5	NS
Peak DP (mm Hg·beats/min)	19,882 ± 1,329	16,949 ± 1,568	NS
Change in DP (mm Hg·beats/min)	11,468 ± 1,060	8,796 ± 1,222	NS

Mean values presented with the standard error of the mean as index of dispersion.

were considered to have significant CAD if any of the major coronary arteries had luminal narrowing of 75% or greater. Three-vessel CAD was defined as simultaneous obstruction in proximal portions of the left anterior descending artery, right coronary artery and left circumflex coronary artery or its first large marginal branch.[12] Isolated left main CAD would have been scored as equivalent to 2-vessel CAD, but in this series it occurred only in patients with additional 3-vessel CAD.

Exercise electrocardiography: Exercise electrocardiography was performed on a treadmill using standard or modified Bruce protocols. Although target HRs were sought, clinical studies were terminated when indicated because of anginal chest pain, a reduction in systolic blood pressure of 10 mm Hg or more, the development of 3 consecutive ventricular premature complexes or limiting fatigue, dyspnea or light-headedness. Twelve-lead electrocardiograms were recorded after each minute of exercise. The baseline HR and baseline amount of ST-segment depression were determined from the upright electrocardiogram at rest, recorded before exercise.

The magnitude of ST-segment depression (in microvolts) to the nearest 25 μV was determined by measuring the ST-segment displacement below the end of the PR segment at a point 70 ms after the J point, using a ruler calibrated to 0.25 mm. Six to 8 electrocardiographic complexes were measured in each lead. Standard amplitude calibration (1 mm = 100 μV) was used.

The HR-related change in ST-segment depression (ST/HR slope in μV/beat/min) was calculated according to a previously reported technique[12–14] from measured ST-segment depression and HR separately for leads aVF, V_5 and V_6. Each electrocardiographic lead produced exercise data points that related ST-segment depression as a dependent variable to heart rate as an independent variable. The slope derived from linear regression analysis of the final 3 points was compared with slopes obtained by including progressively earlier points.[12–14] For each patient, the highest calculated ST/HR slope with a statistically significant correlation coefficient (maximal ST/HR slope) from among the 3 leads analyzed was selected as the test result.

In addition, exercise tests were evaluated using standard electrocardiographic criteria[1]: A type 1 response was defined as 1 mm or more of downsloping (type 1a) or horizontal (type 1b) ST-segment depression, a type 2 response as 1 mm or greater of upsloping ST-segment depression, and a negative test as less than 1 mm of ST-segment depression.[1] Patients with a type 1 response were also evaluated for the presence of stage 1 onset of ST-segment depression, ST-segment depression persisting longer than 8 minutes, and for the presence of ST-segment depression of at least 2 mm.

Definitions of test performance: The *sensitivity* of a test criterion for recognition of 3-vessel CAD was defined as the percentage of patients with 3-vessel CAD who had a positive test result according to that test criterion. The *specificity* of a test criterion for 3-vessel CAD was defined as the percentage of patients without 3-vessel CAD who had a negative test result according to that test criterion. *Overall test accuracy* was defined as the percentage of patients correctly diagnosed as either having or not having 3-vessel CAD; this was the proportion of combined true-positive and true-negative test results based on each test criterion. The *positive predictive value* of a test criterion for 3-vessel CAD was defined as the percentage of patients with a positive test result who had 3-vessel CAD.

Data analysis: Electrocardiographic criteria were compared in terms of test sensitivity, specificity, positive predictive value and overall test accuracy. Because predictive value and test accuracy depend on population prevalence of disease,[5,15,16] observed sensitivity and specificity data were used to calculate positive predictive value and overall test accuracy over a wide range of 3-vessel CAD prevalence to assess test applicability in varying populations. To compare group mean values between subsets of patients, the Student *t* test for unpaired samples was used.

Results

Distribution of disease and subgroup characteristics: The group comprised 42 men and 8 women whose mean age was 53 years (range 31 to 74). Eighteen patients had 3-vessel CAD, including 5 with additional left main CAD; 22 had 2-vessel, 6 had 1-vessel and 4 had no significant CAD. At the time of exercise testing, 56% of the patients (10 of 18 with 3-vessel and 18 of 32 with less than 3-vessel CAD) were taking β-adrenergic blocking drugs, and 22 (44%) had a history of myocardial infarction.

The exercise performance of the 18 patients with 3-vessel CAD and the 32 patients with no, 1- or 2-vessel CAD are compared in Table I. Patients with 3-vessel CAD were older, had a greater amount of ST-segment depression at end exercise, and exercised for a significantly shorter period. However, patients with and without 3-vessel CAD were similar with respect to peak HR achieved, exercise HR response, systolic blood pressure response and double product achieved during

TABLE II Recognition of Three-Vessel Coronary Artery Disease by Exercise Electrocardiographic Criteria

Test Criteria	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Overall Test Accuracy (%)	Negative Predictive Value (%)
Type 1a response	33	78	46	62	68
Type 1b response	44	78	53	66	71
Type 1 response	78	56	50	64	82
and stage 1 onset	56	72	53	66	74
and duration ≥8 min	44	75	50	64	71
and ST depression ≥2 mm	61	75	58	70	77
Type 1 and 2 responses	100	38	47	60	100
ST/HR slope ≥6.0 (μV/beat/min)	78	97	93	90	89

ST/HR slope = maximal ST segment/heart rate slope (see text).

exercise, although trends toward lower performance can be seen in patients with 3-vessel CAD.

ST-segment/heart rate relation: The exercise ST/HR slope calculated for each patient is shown relative to the extent of CAD in Figure 1. The maximal ST/HR slope was 1.3 ± 0.3 μV/beat/min (range 0.8 to 2.2) in patients with no significant CAD, 2.2 ± 0.5 (range 1.2 to 4.2) in patients with 1-vessel CAD, 3.5 ± 0.4 (range 0.7 to 7.4) in patients with 2-vessel CAD and 9.1 ± 1.2 (range 2.8 to 20.0) in patients with 3-vessel CAD. All differences were statistically significant ($p < 0.001$ to $p < 0.05$) except for comparison of patients with 1-vessel and those with no CAD. The maximal ST/HR slope in the 5 patients with combined 3-vessel and additional left main CAD was 10.8 ± 1.3 (range 8.2 to 15.7). This is not statistically different from the maximal ST/HR slope in the 13 patients with 3-vessel CAD alone (8.5 ± 1.5 [range 2.8 to 20.0]).

The ability of the maximal ST/HR slope to correctly distinguish patients with 3-vessel CAD from among a similarly symptomatic group with less extensive CAD is shown in Table II. Using a maximal ST/HR slope of ≥6.0 μV/beat/min as a test criterion for the recognition of 3-vessel CAD has a sensitivity of 78%, specificity of 97%, positive predictive value of 93% and an overall test accuracy of 90%.

Standard electrocardiographic criteria: Standard evaluation of the exercise electrocardiograms revealed a type 1 response in 28 patients (56%), a type 2 response in 10 patients (20%) and a negative response in 12 patients (24%). The type 1 responses were further subclassified into type 1a (13 patients) and type 1b (15 patients).

The ability of standard electrocardiographic criteria to distinguish patients with 3-vessel CAD from other patients is also shown in Table II. A type 1 response as a test criterion for the identification of 3-vessel CAD has a sensitivity of 78%, specificity of 56% and a positive predictive value of only 50%. The addition of either stage 1 onset of ST-segment depression, prolonged duration of ST-segment depression, or ST-segment depression of 2 mm or greater to a type 1 response increases test specificity at the expense of lower sensitivity, without significantly improving the positive predictive value. The inclusion of type 2 in addition to type 1 responses as a positive test criterion improves the sensitivity for detecting 3-vessel CAD in this group to 100%, but decreases specificity to 38%. The overall test accuracy using standard electrocardiographic analysis, including combinations of criteria, ranges from 60 to 70%.

Effect of beta-blocking drugs: The effects of β-blocking drugs on exercise performance, electrocardiographic findings and the ST/HR slope are listed in Table III. Among patients with 1-, 2- and 3-vessel CAD, the mean ST/HR slope is the same in subgroups with the same extent of CAD, regardless of the presence or

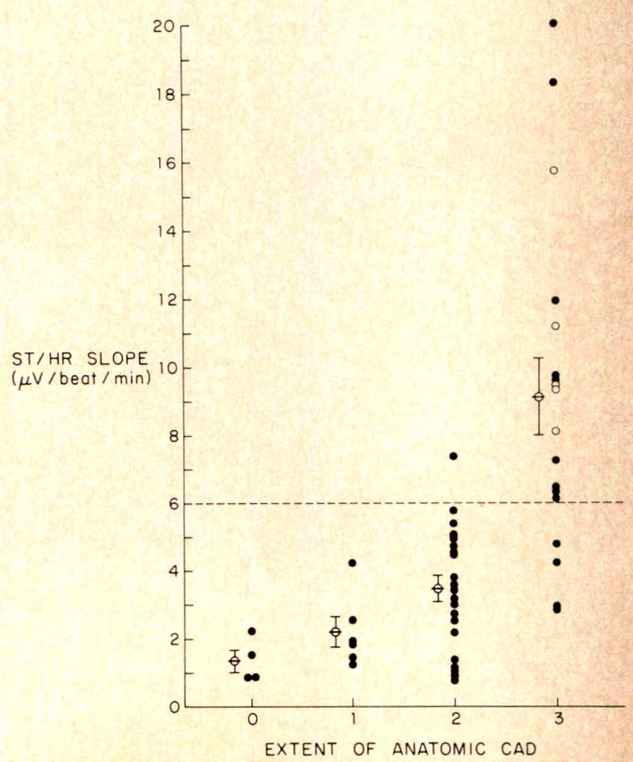

FIGURE 1. Relation of maximal ST-segment/heart rate (ST/HR) slope to the extent of coronary artery disease (CAD). A slope of 6.0 μV/beat/min (**broken line**) separates patients with 3-vessel disease from others with overall test accuracy of 90%. Patients with additional left main disease are represented by **open circles.**

TABLE III Comparison of Exercise Test Findings in Patients With and Without Beta-Adrenergic Blocking Drugs, According to Extent of Coronary Artery Disease

Exercise Findings	0-, 1- and 2-Vessel CAD		3-Vessel CAD	
	With β Blocker	Without β Blocker	With β Blocker	Without β Blocker
ST/HR slope (μV/beat/min)	2.9 ± 0.4	3.1 ± 0.5	8.8 ± 1.9	9.5 ± 1.2
Duration of ex (stages)	2.6 ± 0.3	2.6 ± 0.4	1.9 ± 0.3	2.1 ± 0.3
Magnitude of ST depression (mm)	0.8 ± 0.2	1.0 ± 0.2	1.4 ± 0.2	2.8 ± 0.4*
Peak HR (beats/min)	128 ± 6	138 ± 8	109 ± 7	136 ± 7*
Change in HR (beats/min)	55 ± 5	66 ± 8	44 ± 5	58 ± 7
Peak SBP (mm Hg)	146 ± 8	158 ± 8	119 ± 6	160 ± 11*
Change in SBP (mm Hg)	27 ± 7	34 ± 7	13 ± 2	36 ± 8*
Peak DP (mm Hg·beats/min)	18,958 ± 1,529	21,855 ± 1,893	13,136 ± 1,333	21,716 ± 2,175†
Change in DP (mm Hg·beats/min)	10,215 ± 1,228	14,505 ± 1,553*	6,091 ± 859	12,177 ± 2,009*

All values are expressed as mean ± standard error of the mean.
* $p < 0.05$; † $p < 0.001$.
CAD = coronary artery disease; DP = double product; ex = exercise; HR = heart rate; SBP = systolic blood pressure; ST/HR slope = maximal ST segment/heart rate slope (see text).

absence of β blockade. Constancy of the ST/HR slope was found in therapeutic subgroups of patients with 3-vessel CAD despite the significantly greater magnitude of ST depression, higher HRs, and higher blood pressures achieved by patients not taking β-blocking drugs. A similar relation is seen in the patients with less than 3-vessel CAD, and for the change in HR with exercise in both groups, but these differences do not achieve statistical significance. All patients with less than 3-vessel CAD are grouped for clarity in Table III, although findings apply to individual subgroups as well.

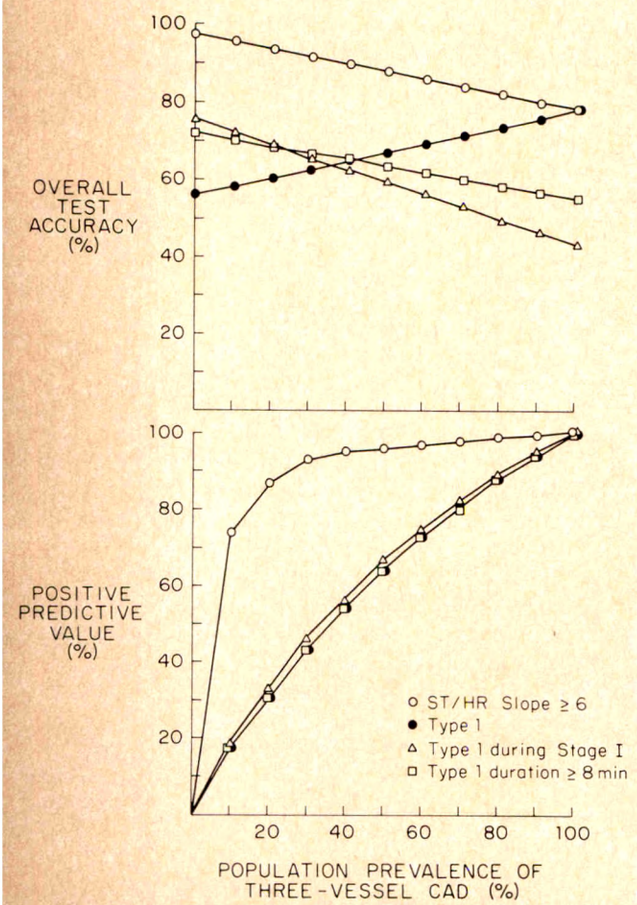

FIGURE 2. Effect of population prevalence on overall test accuracy and positive predictive value of various test parameters for the identification of 3-vessel coronary artery disease (CAD). Greater test accuracy and predictive value of the ST-segment/heart rate (ST/HR) slope are apparent at any disease prevalence. The method is strong in the prevalence range, where 3-vessel disease is found in most clinical populations.

Bayesian analysis: Figure 2 shows the positive predictive value and overall test accuracy for the maximal ST/HR slope, type 1 response, stage 1 onset of ST-segment depression and prolonged duration of ST-segment depression as a calculated function of the prevalence of 3-vessel CAD in the group. The maximal ST/HR slope has the greatest positive predictive value and overall test accuracy for any assumed population.

Discussion

Our data confirm the ability of a rate-normalized measure of exercise-induced ST-segment depression, the ST/HR slope, to identify patients with 3-vessel disease within a CAD population. In contrast is the significantly lower overall test accuracy of standard electrocardiographic criteria for the detection of extensive disease. These findings support the theoretical basis of ST-segment analysis developed by Elamin et al,[12,13] who demonstrated the ability of the ST/HR slope to accurately assess the presence or absence of CAD and to precisely quantify the severity of CAD according to 1-, 2-, and 3-vessel involvement with no overlap between groups.

Rationale for ST/HR slope analysis: The ST/HR slope is an index of functional myocardial ischemia.[12–14] Excellent correlation has been shown between myocardial oxygen consumption and HR in normal subjects, in patients with CAD and in experimental animals.[17–19] From these data, it is apparent that myocardial ischemia should be provoked with smaller increases in HR in patients with more extensive CAD. In addition, ST-segment depression with exercise can be related to the extent of myocardial ischemia caused by underlying CAD,[20–22] even though ST-segment depression alone is not a highly sensitive predictor of CAD in any given patient.[23,24] These observations suggest that ST-seg-

ment depression associated with a smaller increase in HR during exercise should reflect more severe myocardial oxygen supply-demand imbalance than the same magnitude of ST depression occurring with a greater HR response. In effect, the ST/HR slope method normalizes ST-segment depression for the extent of augmentation of myocardial oxygen demand occurring during exercise, and this normalization appears independent of the duration of effort.

Effect of beta-blocking drugs: In patients who were taking β-blocking drugs, no difference in mean ST/HR slopes was found compared with patients with a similar extent of CAD who were not taking these drugs. This finding is in agreement with that Kardash et al,[14] who found no difference in ST/HR slope in 21 patients tested both with and without β-blocking therapy.

Beta-blocking drugs can reduce the magnitude of exercise-related ST-segment depression[25,26] and also decrease the HR response to exercise.[25–27] Because the slopes of lines relating myocardial oxygen consumption to HR during exercise in subjects given β-blocking drugs do not significantly differ from those not receiving drugs,[27] it might be predicted that the observed ST/HR slope in patients treated with β-blocking therapy would remain constant despite clinical improvement with medication. Our data suggest that a parallel decrease in ST-segment depression and HR response to exercise is reponsible for the observed independence of the ST/HR slope from β blockade.

Standard electrocardiographic criteria: Limitations of the standard exercise electrocardiogram[1–8,15,16] are highlighted by our findings. Although horizontal or downsloping ST-segment depression (type 1 response) identified 3-vessel CAD with a sensitivity of 78%, specificity was only 56% and the positive predictive value only 50%. Therefore, this standard electrocardiographic criterion is of limited accuracy in populations with a nonpredominance of 3-vessel CAD. Tightening electrocardiographic criteria for a positive test to include only type 1 responses occurring during stage 1, or those associated with prolonged ST-segment depression or with 2 mm or greater ST-segment depression, improved test specificity, but only at the cost of significant decreases in test sensitivity. Conversely, broadening the criteria for a positive test to include upsloping ST depression (type 2 response) increased test sensitivity at the cost of specificity.

Bayesian analysis: Assuming constant test sensitivity and specificity, the predictive value and overall test accuracy of any test criterion can be mathematically calculated for any postulated prevalence of disease.[5,15,16] This allows for the prediction of test applicability in varying hypothetic populations. Comparison of the calculated overall test accuracy and positive predictive value of the ST/HR slope, type 1 response, stage 1 onset of ST-segment depression and prolonged type 1 ST-segment depression for the identification of 3-vessel CAD in populations with varying prevalence of 3-vessel CAD suggests the diagnostic advantage of the maximal ST/HR slope. This advantage of the ST/HR slope method in calculated test accuracy and positive predictive value is greatest over the CAD prevalence range of 10 to 50%, which is the prevalence range most commonly found in clinical populations undergoing evaluation for known or suspected CAD.[28,29] Thus, incorporation of ST/HR slope analysis into exercise electrocardiographic criteria for recognition of 3-vessel CAD should improve true-positive diagnoses without markedly increasing false-positive diagnoses in patients with CAD.

Limitations of study design: Findings favorable to the ST/HR slope analysis emerge despite intrinsic study design bias against the method. Because our study was retrospective, there were fewer than optimal numbers of data points available for each patient. The available HR increments for each patient were large, reducing test precision. Furthermore, we evaluated only 3 leads, with less precise measurement of ST-segment change compared with previous analyses.[12–14] Nevertheless, even with these limitations, improved accuracy of the exercise electrocardiogram is clear.

An additional limitation bearing on general applicability of the ST/HR slope method involves patient selection in our study. Although consecutive patients who met entry criteria form the basis of this report, we cannot assume that the group studied is representative, because all patients by definition underwent angiography. Catheterization in this group might have been based on potentially predictive symptoms, and in some cases may have been prompted by the electrocardiographic findings at exercise testing. Although in no case was the ST/HR slope a pretest consideration, prospective validation is required to exclude possible bias introduced by otherwise unrecognized electrocardiographic changes.

Implications: The ability of the ST/HR slope to identify the extent of CAD has several important implications. First, noninvasive identification of patients with 3-vessel CAD may be possible with a high degree of sensitivity and specificity, even in the presence of β-blocking drugs. Second, the method may provide the ability to evaluate progression of CAD in an individual patient by following serial ST/HR slopes. Third, patients may be followed up after coronary artery bypass surgery or coronary angioplasty for occult graft closure or reocclusion by comparing an immediate postprocedure ST/HR slope with subsequent tests. Finally, the ST/HR slope analysis may provide more accurate understanding of "false-positive" electrocardiographic responses to exercise associated with abnormal loading conditions and with drugs, if, as expected, the ST-segment–heart rate relation is different in these populations than in patients with CAD.

The number of possible uses for the ST/HR slope highlight the importance of further prospective validation of the technique. However, the present slope analysis is cumbersome for routine application, making a rapid and more standardized method of analysis an important goal. This may be accomplished by computerized measurement of ST-segment displacement combined with computerized linear regression analysis.

Effect of Coffee on Exercise-Induced Angina Pectoris Due to Coronary Artery Disease in Habitual Coffee Drinkers

KENNETH M. PITERS, MD, ANTONIO COLOMBO, MD, HAROLD G. OLSON, MD, and SAMUEL M. BUTMAN, MD

The acute effects of coffee on exercise-induced angina were studied in 17 men with coronary artery disease using a double-blind treadmill protocol. Ingestion of either 1 or 2 cups of caffeinated coffee increased the exercise duration until onset of angina (8 and 12%, respectively, $p < 0.05$), whereas decaffeinated coffee had no effect. The extent of ST-segment depression and the heart rate-blood pressure product at angina were similar after drinking caffeinated and decaffeinated coffee. Exercise duration until 0.1 mV of ST-segment depression, as well as the heart rate, blood pressure and double product at angina and at 0.1 mV of ST-segment depression were similar after drinking caffeinated or decaffeinated coffee. The mean serum caffeine levels (± standard deviation) after ingestion of 1 and 2 cups of caffeinated coffee were 1.97 ± 1.0 and 3.89 ± 1.6 μg/ml, respectively. The acute ingestion of 1 to 2 cups of caffeinated coffee had no deleterious effect on exercise-induced angina pectoris in patients with coronary artery disease. (Am J Cardiol 1985;55:277–280)

It has been estimated that 82% of persons older than age 18 years in the United States consume an average of 186 mg/day of caffeine in coffee, tea, cola beverages and over-the-counter prescriptions.[1] Although a limited amount of data on the arrhythmogenicity of caffeine is available,[2,3] its effect on exercise-induced angina pectoris is unknown. Accordingly, we designed a double-blind treadmill protocol to assess the acute effects of caffeinated and decaffeinated coffee on exercise-induced angina pectoris in patients with chronic stable angina due to coronary artery disease (CAD).

Methods

Seventeen male subjects with chronic stable angina and an abnormal exercise test limited by angina with 0.1 mV or greater horizontal or downsloping ST depression were selected. The patients ranged in age from 40 to 74 years (mean ± standard deviation 59 ± 9). Ten patients were in New York Heart Association class II, and 7 were in class III. All 17 patients had CAD proved by angiography with 75% luminal narrowing in at least 1 major artery. Two patients had 1-vessel CAD, 7 had 2-vessel CAD and 8 had 3-vessel CAD; none had left main CAD. The left ventricular ejection fraction was 65 ± 11% (mean ± standard deviation) (range 41 to 83%). All patients consumed at least 1 cup of coffee daily. Daily coffee consumption averaged 3.7 cups per patient (range 1 to 7).

Patients were excluded if they had myocardial infarction within 3 months, unstable angina, chronic left or right bundle branch block, symptomatic congestive heart failure, complex ventricular arrhythmias (Lown class III or higher) seen on the electrocardiogram before exercise, or valvular heart disease. Also excluded were patients who took quinidine, procainamide or digitalis. Patients with hiatal hernia, esophagitis, peptic ulcer disease or gallbladder disease were also excluded.

Patients were studied on 3 consecutive days in the fasting state without receiving their morning antianginal therapy. Seven of the 17 patients were taking chronic oral propranolol (80 to 200 mg/day in divided doses; mean 114 mg/day). One patient was taking nifedipine 30 mg/day. The other 9 patients were taking nitrates alone. Patients served as their own control subjects over the 3-day study period. No patient smoked cigarettes, coffee or tea for 12 hours before exercise.

Patients underwent paired Bruce protocol treadmill tests each day, totaling 6 tests over 3 days. The first treadmill test served as a control. After 1 hour of rest, 2 cups of hot black coffee were consumed over 20 minutes. On any given day this consisted randomly of either 2 cups of caffeinated coffee, 2 cups of decaffeinated coffee, or a combination of 1 cup of each. The combination of decaffeinated coffee with caffeinated coffee blinded the administration of 1 cup of caffeinated coffee to both patient and observer. Thirty minutes after coffee ingestion, blood was drawn for caffeine levels and a second treadmill test was performed. Patients were instructed to stop exercise when they experienced angina as they would with ordinary activity. Blood pressures were obtained every 90 seconds and with angina at end exercise.

* Values are expressed as mean ± 1 standard deviation. † $p < 0.05$ compared with control.
Abbreviations as in Table I.

Electrocardiographic leads aVF, V_1 and V_5 were monitored continuously during exercise. Exercise ST depression beyond baseline ST at rest was measured from electrocardiographic recordings in the lead with the most shift. ST depression was evaluated 80 ms past the J point on 3 consecutive QRS complexes.

Exercise duration until 0.1 mV of ST depression and exercise duration until onset of angina were measured from electrocardiographic recordings. Heart rate-blood pressure product was calculated at the time of 0.1 mV ST depression and at angina at end exercise.

Two cardiologists performed the exercise tests in an identical manner in the same air-conditioned room. Each patient was supervised by the same cardiologist over the 3-day period.

Coffee was prepared by mixing 8 ounces of heated water with 1 heaping teaspoon of instant coffee (Taster's Choice® caffeinated and decaffeinated brands), with no milk or sugar.

Caffeine levels were assayed by Smith, Kline and French Laboratories using high pressure liquid chromatography, accurate to 0.5 μg/ml.[4]

Repeated measures analysis of variance was used to compare all 6 treatments (consisting of 3 control treadmill tests before and 3 study treadmill tests after the 3 coffee combinations). Both rest and exercise data were examined. In cases of significant F values, Scheffe's test was used to ascertain which pairs of means were significantly different. This allowed comparison of the 3 treatments of decaffeinated coffee, 1 and 2 cups of caffeinated coffee. In addition, patients who took propranolol were compared with those who did not by a split-plot analysis of variance with least squares analysis design. Statistical significance was defined as $p < 0.05$. Data are presented as mean ±1 standard deviation.

Results

There was no significant change in baseline mean heart rate at rest, systolic blood pressure at rest or heart rate-blood pressure product at rest after the ingestion of any of the 3 coffee combinations (Table I).

There was no significant difference in mean exercise duration until the development of angina after 2 cups of decaffeinated coffee compared with results in the control treadmill tests. However, 1 and 2 cups of caffeinated coffee resulted in significant prolongation of exercise over controls (mean increase of 37 seconds for 1 cup and 53 seconds for 2 cups of caffeinated coffee, $p < 0.05$) (Table II).

There was no significant difference in the mean heart rate, systolic blood pressure and heart rate-blood pressure product at angina on treadmill tests after any of the 3 coffee combinations. There was a trend toward an increase in heart rate-blood pressure product at angina after 2 cups of caffeinated coffee which did not reach statistical significance (Table II).

There was no significant difference in the extent of ST depression at angina after any of the 3 coffee combinations.

There was no significant difference in exercise duration until onset of 0.1 mV of ST depression after any of the 3 coffee combinations (Table III). Although there was a trend toward an increased exercise duration until 0.1 mV of ST depression after 2 cups of caffeinated coffee, this did not reach statistical significance. In addition, there was no significant change in heart rate, systolic blood pressure or heart rate-blood pressure product at 0.1 mV of ST depression after any of the 3 coffee combinations (Table III).

The 7 patients who received long-term therapy with propranolol were analyzed separately and compared with the 10 patients who did not receive propranolol. Rest and peak exercise heart rate and blood pressure before and after coffee ingestion were similar in both groups. In addition, there was no statistically significant difference between the 2 groups in exercise time to 0.1 mV ST depression or to angina after any of the 3 coffee combinations.

TABLE III Exercise Values at 0.1 mV of ST Depression Before and After Coffee Ingestion

Value*	Control	Decaffeinated Coffee	Control	1 Cup of Caffeinated Coffee	Control	2 Cups of Caffeinated Coffee
Exercise duration (sec)	298 ± 157	307 ± 153	312 ± 132	313 ± 144	290 ± 136	319 ± 132
HR (beats/min)	115 ± 15	114 ± 17	112 ± 16	111 ± 15	115 ± 15	115 ± 16
SBP (mm Hg)	151 ± 17	149 ± 16	153 ± 18	149 ± 18	148 ± 18	150 ± 16

TABLE IV Prevalence and Frequency of Rest and Exercise Premature Atrial Contractions and Premature Ventricular Contractions

	Control	Decaffeinated Coffee	Control	1 Cup of Caffeinated Coffee	Control	2 Cups of Caffeinated Coffee
Premature Atrial Contractions						
No. of pts with ≥1 PAC on rest ECG	0	0	3	1	1	1
No. of PACs on rest ECG (all 17 pts)	0	0	12	1	1	1
No. of pts with ≥1 PAC with exercise	3	3	5	4	3	2
No. of PACs with exercise (all 17 pts)	18	9	17	14	8	3
Premature Ventricular Contractions						
No. of pts with ≥1 PVC on rest ECG	0	1	2	0	0	1
No. of PVCs on rest ECG (all 17 pts)	0	4	2	0	0	1
No. of pts with ≥1 PVC with exercise	3	4	3	5	7	5
No. of PVCs with exercise (all 17 pts)	11	12	24	45	20	17

ECG = electrocardiogram; PAC = premature atrial contraction; PVC = premature ventricular contraction.

There was no significant increase in the prevalence of resting or exercise-induced premature atrial or ventricular contractions after any of the coffee combinations (Table IV). One patient with unifocal premature ventricular contractions on a control treadmill test experienced an increased number but not complexity of premature ventricular contractions during exercise after 1 and 2 cups of caffeinated coffee.

The mean serum caffeine level 30 minutes after 2 cups of decaffeinated coffee was 0.73 ± 0.3 μg/ml. The serum caffeine level after 1 cup of caffeinated coffee was 1.97 ± 1.0 μg/ml and after 2 cups of caffeinated coffee was 3.89 ± 1.6 μg/ml. The mean serum caffeine level after 2 cups of caffeinated coffee was significantly higher than after 1 cup of caffeinated coffee and both were significantly higher than after 2 cups of decaffeinated coffee ($p < 0.01$).

Discussion

The principal pharmacologic agent in coffee is generally accepted to be caffeine—a methylated xanthine. One cup of coffee contains about 85 mg of caffeine. The per capita intake of caffeine in the United States has been estimated to be 200 mg/day,[1] equivalent to 2 cups of caffeinated coffee.

We evaluated the effects of coffee on exercise in 17 men with chronic stable angina and proved CAD, who were habitual coffee drinkers (mean, 3.7 cups/day). Two cups of caffeinated coffee had no deleterious effects on exercise-induced angina, ST depression, premature ventricular contractions or exercise duration. Exercise duration until angina was significantly prolonged after both 1 and 2 cups of caffeinated coffee (mean increase, 37 seconds after 1 cup and 53 seconds after 2 cups of caffeinated coffee). This increase in the exercise time to development of angina after coffee ingestion was accompanied by a statistically insignificant trend toward a higher heart rate-blood pressure product (an index of myocardial O_2 demand), with no change in the extent of ST depression at angina compared with results in the control treadmill tests.

The mechanisms for this increase in exercise time to angina after caffeinated coffee are speculative but could include central nervous system stimulant and analgesic properties,[5] shift in substrate use from carbohydrate to free fatty acids,[6] increase in myocardial O_2 supply, decrease in myocardial O_2 demand, or any combination of these factors.

Explanation of the increase in exercise duration purely by central nervous system stimulation and delay

in perception of angina would seem unlikely, because one would expect more profound ischemia at angina, whereas similar degrees of ST depression were manifested after caffeinated and decaffeinated coffee. However, central nervous system stimulation may be partially responsible for the increased exercise time after caffeinated coffee.

Previous studies support the contention that caffeine acutely increases the work of the heart in normal subjects,[7,8] although the caffeine effect on cardiac work during exercise is unknown in patients with CAD. The trend toward increased cardiac work at the onset of angina (at similar degrees of ischemia) after caffeinated coffee occurred with increased exercise times. This implies a beneficial shift in the O_2 supply-demand ratio. Diuretic properties of caffeine[9] may mimic a nitrate effect by decreasing preload and therefore wall tension and myocardial O_2 consumption at a given double product. Alternatively, coronary flow may have improved.

The effect of the methylxanthines on coronary blood flow, especially in humans, remains controversial. The belief that they might increase coronary blood flow has led to their use in patients with angina.[10] Animal studies of the effects of xanthines on coronary flow are conflicting,[11,12] whereas human studies are lacking. In this study, exercise duration before 0.1 mV of ST depression was prolonged after 2 cups of caffeinated coffee, but because this prolongation was not significant, no definite conclusion regarding coronary flow can be reached.

The possibility that training effect accounted for the increased exercise time to angina after caffeinated coffee is unlikely, because there was no such increase after decaffeinated coffee compared with results of the control treadmill tests. Moreover, there could be no cumulative training effect over the 3-day study period because the coffee combinations were given randomly, resulting in an equal distribution of the coffee combinations between the first and third days of the study.

Resting hemodynamic variables were unaffected by caffeine in the patients in this study. This is consistent with the hemodynamic study of Gould et al,[7] although data on normal volunteers suggest that an increase in blood pressure should accompany the ingestion of 2 cups of caffeinated coffee.[13] Blood levels of caffeine, similar to other studies after 2 cups of caffeinated coffee,[2] indicate adequate absorption of the drug in our patients. Because the 10 patients who did not receive propranolol had similar rest and exercise heart rates and blood pressures before and after coffee ingestion (similar to those who did take propranolol), it is unlikely that the residual effects of propranolol 12 hours after the last dose account for the blunted hemodynamic response seen in the entire group. Patients with CAD may behave differently than normal subjects after coffee ingestion. Alternatively, the lack of effect of coffee on hemodynamics at rest in our study may be explained by tolerance to the effects of caffeine with chronic coffee use. Tolerance to caffeine has been described and can result in a blunted hemodynamic response within 1 to 4 days of initiation.[14] All patients in our study drank coffee chronically. Perhaps exercise duration in our patients would have decreased had the heart rate-blood pressure products at rest increased with coffee ingestion.

energy efficient

Inocor® I.V.

(AMRINONE)

A major advance toward ideal inotropic therapy

energy efficient
Inocor® I.V.
(AMRINONE)

Instead of catecholamines for the short-term management of heart failure

- Independent of the effects of digitalis and catecholamines
- Hemodynamics rapidly improved
- Heart rate and blood pressure not significantly changed... has not been shown to increase risk of arrhythmias
- Can be used in patients with myocardial ischemia
- Benefits sustained during therapy... no evidence of tachyphylaxis
- Easy to administer

Patients receiving INOCOR should be carefully monitored with the following laboratory studies: platelet counts, liver enzymes, fluid and electrolyte changes, and renal function. Hypokalemia should be corrected by potassium supplementation in advance of or during amrinone use.

INOCOR lactate injection, brand of amrinone lactate, represents a new class of cardi inotropic agents with vasodilator activity, distinct from digitalis glycosides catecholamines.

INDICATIONS AND USAGE (INOCOR lactate injection is indicated for the short-te management of congestive heart failure in patients who can be closely monitored a who have not responded adequately to digitalis, diuretics, and/or vasodilators.)

INOCOR lactate injection is indicated for the short-term management of conge tive heart failure. Because of limited experience and potential for serious adver effects (see ADVERSE REACTIONS), INOCOR should be used only in patients who c be closely monitored and who have not responded adequately to digitalis, diureti and/or vasodilators. Although most patients have been studied hemodynamically periods only up to 24 hours, some patients were studied for longer periods a demonstrated consistent hemodynamic and clinical effects. The duration of thera should depend on patient responsiveness.

CONTRAINDICATIONS INOCOR lactate injection is contraindicated in patients w are hypersensitive to it.

It is also contraindicated in those patients known to be hypersensitive to bisulfit

PRECAUTIONS *General*: INOCOR lactate injection should not be used in patients w severe aortic or pulmonic valvular disease in lieu of surgical relief of the obstructi Like other inotropic agents, it may aggravate outflow tract obstruction in hypertrop subaortic stenosis.

During intravenous therapy with INOCOR lactate injection, blood pressure a heart rate should be monitored and the rate of infusion slowed or stopped in patie showing excessive decreases in blood pressure.

Patients who have received vigorous diuretic therapy may have insuffici cardiac filling pressure to respond adequately to INOCOR lactate injection, in whi case cautious liberalization of fluid and electrolyte intake may be indicated.

Supraventricular and ventricular arrhythmias have been observed in the ve high-risk population treated. While amrinone per se has not been shown to arrhythmogenic, the potential for arrhythmia, present in congestive heart failure its may be increased by any drug or combination of drugs.

Thrombocytopenia and hepatotoxicity have been noted (see ADVERS REACTIONS).

LABORATORY TESTS *Fluid and electrolytes*: Fluid and electrolyte changes and ren function should be carefully monitored during amrinone lactate therapy. Improveme in cardiac output with resultant diuresis may necessitate a reduction in the dose diuretic. Potassium loss due to excessive diuresis may predispose digitalized patie to arrhythmias. Therefore, hypokalemia should be corrected by potassium supp mentation in advance of or during amrinone use.

DRUG INTERACTIONS In a relatively limited experience, no untoward clinical ma festations have been observed in patients in whom INOCOR lactate injection was us concurrently with the following drugs: digitalis glycosides, lidocaine, quinidine, me prolol, propranolol; hydralazine, prazosin; isosorbide dinitrate, nitroglycerine; chlorth done, ethacrynic acid, furosemide, hydrochlorothiazide, spironolactone, captop heparin, warfarin, potassium supplements, insulin, diazepam.

One case of excessive hypotension was reported when amrinone was us concurrently with disopyramide.

Until additional experience is available, concurrent administration with Norpac disopyramide should be undertaken with caution.

USE IN ACUTE MYOCARDIAL INFARCTION INOCOR is not recommended for use acute myocardial infarction.

USE IN CHILDREN Safety and effectiveness in children have not been established.

USE IN PREGNANCY *Pregnancy category C*: In New Zealand white rabbits, amrinor has been shown to reduce fetal skeletal and gross external malformations at oral dos of 16 mg/kg and 50 mg/kg that were toxic for the rabbit. Studies in French Hy/Cr rabb using oral doses up to 32 mg/kg/day did not confirm this finding. No malformatio were seen in rats receiving amrinone intravenously at the maximum dose use 15 mg/kg/day (approximately the recommended daily IV dose for patients with co gestive heart failure). There are no adequate and well-controlled studies in pregna women. Amrinone should be used during pregnancy only if the potential bene justifies the potential risk to the fetus.

USE IN NURSING MOTHERS Caution should be exercised when amrinone administered to nursing women, since it is not known whether it is excreted in hum milk.

ADVERSE REACTIONS *Thrombocytopenia*: Intravenous INOCOR lactate injecti resulted in platelet count reductions to below 100,000/mm³ in 2.4% of patients.

Gastrointestinal effects: Gastrointestinal adverse reactions reported with INOCO lactate injection during clinical use included nausea (1.7%), vomiting (0.9%), abdomir pain (0.4%), and anorexia (0.4%).

Cardiovascular effects: Cardiovascular adverse reactions reported with INOCO lactate injection include arrhythmia (3%) and hypotension (1.3%).

Hepatic toxicity: In dogs, at IV doses between 9 mg/kg/day and 32 mg/kg/da amrinone showed dose-related hepatotoxicity manifested either as enzyme elevatic or hepatic cell necrosis or both. Hepatotoxicity has been observed in man followir long-term oral dosing and has been observed, in a limited experience (0.2%), followir IV administration of amrinone.

Hypersensitivity: There have been reports of several apparent hypersensitivity rea tions in patients treated with oral amrinone for about two weeks. Signs and symptom were variable but included pericarditis, pleuritis, and ascites (one case); myositis wi interstitial shadowing on chest x-ray and elevated sedimentation rate (one case); ar vasculitis with nodular pulmonary densities, hypoxemia, and jaundice (one case). Th first patient died, not necessarily of the possible reaction, while the last two resolve with discontinuation of therapy. None of the cases were rechallenged, so attribution amrinone is not certain, but possible hypersensitivity reactions should be considered any patient maintained for a prolonged period on amrinone.

General: Additional adverse reactions observed in intravenous amrinone clinic studies include fever (0.9%), chest pain (0.2%), and burning at the site of injectic (0.2%).

OVERDOSAGE Doses of INOCOR lactate injection may produce hypotensic because of its vasodilator effect. If this occurs, amrinone administration should b reduced or discontinued. No specific antidote is known, but general measures f circulatory support should be taken.

MANAGEMENT OF ADVERSE REACTIONS *Platelet count reductions*: Asympt matic platelet count reduction (to less than 150,000/mm³) may be reversed within or week of a decrease in drug dosage. Further, with no change in drug dosage, the cou may stabilize at lower than predrug levels without any clinical sequelae. Predrug platel counts and frequent platelet counts during therapy are recommended to assist decisions regarding dosage modifications.

Should a platelet count less than 150,000/mm³ occur, the following actions may b considered:

- Maintain total daily dose unchanged, since in some cases counts have eith stabilized or returned to pretreatment levels.
- Decrease total daily dose.
- Discontinue amrinone if, in the clinical judgment of the physician, risk exceeds th potential benefit.

Gastrointestinal side effects: While gastrointestinal side effects were seen infrequent with IV therapy, should severe or debilitating ones occur, the physician may wish t reduce dosage or discontinue the drug based on the usual benefit-to-ris considerations.

Hepatic toxicity: In clinical experience to date with IV administration, hepatotoxicity ha rarely been observed. If acute marked alterations in liver enzymes occur together wit clinical symptoms, suggesting an idiosyncratic hypersensitivity reaction, amrinon therapy should be promptly discontinued.

If less than marked enzyme alterations occur without clinical symptoms, thes nonspecific changes should be evaluated on an individual basis. The clinician ma wish to continue amrinone and reduce the dosage or discontinue the drug based o the usual benefit-to-risk considerations.

HOW SUPPLIED Ampuls of 20 mL sterile, clear yellow solution containing INOCO 5 mg/mL, box of 5 (NDC 0024-0888-20). Each 1 mL contains INOCOR lactat equivalent to 5 mg base and 0.25 mg sodium metabisulfite in water for injection.

Propranolol-Verapamil Versus Propranolol-Nifedipine in Severe Angina Pectoris of Effort: A Randomized, Double-Blind, Crossover Study

MICHAEL D. WINNIFORD, MD, KAY L. FULTON, RN, JAMES R. CORBETT, MD, CHARLES H. CROFT, MD, and L. DAVID HILLIS, MD

To compare a propranolol-verapamil with a propranolol-nifedipine combination in patients with severe angina of effort, 16 patients (11 men and 5 women, aged 56 ± 8 years [mean ± standard deviation]) with more than 5 episodes/week of angina and a positive exercise tolerance test despite propranolol (229 ± 44 mg/day [range 180 to 360]) were maintained on this dose of propranolol and, in addition, received verapamil (360 mg/day) and nifedipine (60 mg/day) for 3 weeks each in a double-blind, randomized fashion. In comparison with propranolol alone, anginal frequency and nitroglycerin usage were reduced by propranolol-verapamil but not by propranolol-nifedipine. Exercise time (standard Bruce protocol) was similar for the 2 combinations (6.4 ± 2.0 minutes with propranolol-verapamil, 6.6 ± 2.1 minutes with propranolol-nifedipine, difference not significant), but the magnitude of ST-segment depression at peak exercise was less ($p < 0.05$) during propranolol-verapamil (0.03 ± 0.06 mV) than during propranolol alone (0.18 ± 0.07 mV) and propranolol-nifedipine (0.08 ± 0.07 mV). Left ventricular ejection fraction at rest was higher ($p < 0.05$) with propranolol-nifedipine (0.62 ± 0.10) than with propranolol-verapamil (0.58 ± 0.10), but neither differed from ejection fraction at rest with propranolol alone (0.59 ± 0.08). Ejection fraction at peak exercise was similar during all 3 periods. In 2 patients, verapamil caused weakness, lightheadedness, and severe sinus bradycardia (40 to 48 beats/min), and the dosage was reduced (blindly) to 240 mg/day, with the alleviation of bradycardia and associated symptoms. Thus, in patients with severe angina of effort with propranolol alone, the addition of verapamil is more effective than the addition of nifedipine in reducing anginal frequency, nitroglycerin usage, and the magnitude of the electrocardiographic response to exercise. Although both combinations are generally safe and well-tolerated, in an occasional patient symptomatic sinus bradycardia develops during therapy with propranolol-verapamil; therefore, this combination must be given carefully.

(Am J Cardiol 1985;55:281–285)

Over the past 15 years, the β-adrenergic blocking agents, such as propranolol, have been effective in patients with stable angina of effort.[1–5] Later, the calcium antagonists, including verapamil[6–9] and nifedipine,[10,11] have proved efficacious in this patient population. However, some patients have limiting angina despite maximally tolerated doses of propranolol or 1 of the calcium antagonists, and in these patients, a combination of propranolol and a calcium antagonist may be especially beneficial. In fact, previous studies have demonstrated that a propranolol-verapamil combination[12–14] and a propranolol-nifedipine combination[15] are better than either agent alone in patients whose angina is particularly severe. The present randomized, double-blind and crossover study was performed to compare a propranolol-verapamil combination and a propranolol-nifedipine combination in patients with severe angina of effort.

Methods

Study patients: Sixteen patients (11 men and 5 women, aged 56 ± 8 years [mean ± standard deviation]) with limiting angina of effort despite therapy with propranolol (range 180 to 360 mg/day [average 229 ± 44]), were enrolled in the study. Each had more than 5 episodes of typical angina per week and a positive exercise tolerance test (with chest pain and greater

than 0.1 mV ST-segment depression) during propranolol therapy. Selective coronary arteriography was performed in 13 patients, all of whom had significant coronary artery disease (defined as greater than 70% narrowing of luminal diameter) (3-vessel disease in 7, 2-vessel disease in 5 and 1-vessel in 1). The other 3 patients had typical angina as well as historical and electrocardiographic evidence of previous myocardial infarction. One patient had undergone coronary artery bypass surgery in the remote past.

Of the 16 patients, 2 were maintained throughout the study on a stable dose of slow-release transdermal nitroglycerin (10 mg/day). In these patients, several attempts to taper or discontinue nitrates caused a worsening of angina. All patients were instructed to use sublingual nitroglycerin only for relief of anginal episodes. No other cardiac medications were given during the study.

Patients with any of the following were excluded from the study: congestive heart failure, as reflected by cardiomegaly and pulmonary vascular redistribution on chest x-ray; uncontrolled systemic arterial hypertension (diastolic arterial pressure greater than 115 mm Hg); hypotension (systolic arterial pressure less than 90 mm Hg); associated valvular or congenital cardiac disease; renal disease (serum creatinine more than 2.5 mg%); hepatic disease (serum bilirubin more than 2.5 mg%); any terminal illness; certain electrocardiographic abnormalities, including bundle branch block, severe bradycardia (heart rate less than 50 beats/min with propranolol), second- or third-degree atrioventricular block, or atrial flutter or fibrillation; or concomitant therapy with disopyramide or an investigational agent.

Study design: Each patient who entered the study received a maximally tolerated dose of propranolol, which was continued throughout the study. After informed consent was obtained, each received single-blind placebo for 2 weeks, after which he or she was randomly assigned to 1 of 2 groups for the remaining 7 weeks of the study: two 3-week periods of verapamil (360 mg/day in 3 equal doses) and nifedipine (60 mg/day in 3 equal doses), administered in random order and separated by a 1-week period of single-blind placebo. During the 2 periods of combination propranolol-calcium antagonist therapy, neither the physicians nor the patients knew which calcium antagonist was being given.

Variables assessed: *Clinical response to therapy:* Each patient was seen weekly by 1 of us, and the following were quantitated: (1) episodes of angina per week (recorded daily by the patient in a diary), (2) nitroglycerin tablets used per week (assessed by tablet count), and (3) adverse effects (recorded by the patient in a diary).

Exercise tolerance testing: Upright treadmill exercise: At the end of each treatment period, each patient had treadmill exercise testing according to a standard Bruce protocol 1½ to 2 hours after the regularly scheduled morning dose of propranolol and study medication. Exercise was continued until the occurrence of exhaustion, angina of at least moderate severity, frequent ventricular ectopy, or a markedly positive electrocardiographic response. The following variables were measured: (1) heart rate at rest and peak exercise, (2) heart rate-systolic arterial pressure double product at rest and peak exercise, (3) total exercise duration (in minutes), and (4) maximal ST-segment depression (in millivolts) from the isoelectric point.

Supine bicycle exercise with radionuclide ventriculography: After 2 weeks of each treatment, each patient had maximal supine bicycle exercise testing with simultaneous equilibrium-gated blood pool scintigraphy. As with treadmill exercise testing, these studies were performed 1½ to 2 hours after a regularly scheduled morning dose of propranolol and study medication. Exercise was begun at 200 kpm/min and increased incrementally by 200 kpm every 4 minutes until exhaustion, angina of at least moderate severity, or frequent ventricular ectopy. From each of these studies, the scintigraphic response to exercise was assessed, as reflected by left ventricular ejection fraction at rest and peak exercise, as previously described.[8,16,17]

Ambulatory electrocardiographic monitoring: At the end of the second week of each treatment period, ambulatory electrocardiographic (Holter) monitoring was performed for 24 hours, and the tapes were analyzed for PR interval, atrioventricular conduction disturbances and average heart rates.

Serum propranolol and verapamil concentrations: At the end of each treatment period (immediately before treadmill exercise testing), blood was obtained from each patient for the measurement of serum propranolol and verapamil concentrations.

Statistical analyses: All patient diaries, nitroglycerin tablet counts, Holter monitor recordings and exercise tolerance tests (treadmill and supine bicycle) were analyzed without knowledge of the order in which verapamil and nifedipine were given. The clinical characteristics of the patients initially assigned to verapamil were compared with those in the patients initially assigned to nifedipine; there were no differences, confirming that the initial assignment was random. For each variable, a repeated measures analysis of variance was performed to determine if some groups were different from others, after which the Newman-Keuls multiple comparisons procedure was performed. An unpaired t test was used to compare treatment responders and nonresponders. In comparing rest and peak exercise values during treatment with the same pharmacologic agent, the paired t test was used. For all analyses, a p value <0.05 was considered significant.[18,19]

Results

Patient compliance and tolerance of the medications: Patient compliance was excellent during all treatment periods (Table I). Of the 16 patients, 14 tolerated full doses of verapamil and nifedipine without difficulty. In the other 2 (both of whom had a resting heart rate less than 55 beats/min with propranolol alone), full-dose (360 mg/day) verapamil caused weakness, lightheadedness, and a sinus bradycardia of 40 to 48 beats/min with intermittent junctional escape beats. In these, the verapamil dosage was (blindly) reduced to 240 mg/day (120 mg twice daily), with the resultant alleviation of bradycardia and its associated symptoms.

The serum propranolol concentrations were similar during the 3 treatment periods and averaged 196 ± 133 ng/ml (range 32 to 438). The serum verapamil concentrations averaged 313 ± 143 ng/ml (range 130 to 609).

Responses to combination therapy: *Clinical responses to therapy:* Anginal frequency and nitroglycerin usage were similar during treatment with propranolol-verapamil and propranolol-nifedipine (Table I). However, in comparison to propranolol alone, anginal frequency and nitroglycerin usage were significantly reduced only during propranolol-verapamil. The 2 patients who received slow-release transdermal nitroglycerin during the study responded similarly to the 2 combinations (4.0 and 0.3 anginal episodes/week with propranolol-verapamil, 4.3 and 0.3 episodes/week with propranolol-nifedipine, respectively).

In comparison with propranolol alone, 7 patients responded to propranolol-verapamil with a more than 50% reduction in anginal frequency. During propranolol

Compliance	99%	100%	99%

All values are expressed as mean ± standard deviation.
* $p < 0.05$ compared with propranolol alone; † $p < 0.05$ compared with propranolol-verapamil.
ex = exercise; HR = heart rate; LVEF = left ventricular ejection fraction; NTG = nitroglycerin; SAP = systolic arterial pressure.

therapy alone, these 7 "responders" had a significantly higher average heart rate (73 ± 12 beats/min) than the 9 "nonresponders" (63 ± 5 beats/min, $p < 0.05$). In all other respects, the propranolol-verapamil responders and nonresponders were similar. In comparison with propranolol alone, 6 patients responded to propranolol-nifedipine with a more than 50% reduction in anginal frequency. There were no differences in clinical, hemodynamic, electrocardiographic or scintigraphic variables in the 6 propranolol-nifedipine responders and the remaining 10 nonresponders.

During propranolol therapy alone, 1 patient had shortness of breath. During treatment with propranolol-verapamil, 2 patients had constipation. During propranolol-nifedipine treatment, 1 patient complained of flushing, 1 had pedal edema and 1 noted constipation.

Responses to treadmill exercise tolerance testing: At rest and during peak exercise, the heart rate-systolic arterial pressure double products during propranolol-verapamil and propranolol-nifedipine were similar to one another and lower than during propranolol alone (Table I). Total exercise time was similar for the 2 combinations.

Four patients had electrocardiographic voltage criteria for left ventricular hypertrophy,[20] 2 of whom had evidence of left ventricular strain. Each had further ST-segment depression greater than 0.20 mV (average 0.24 ± 0.20 mV) and chest pain during exercise testing. In the 16 patients, the magnitude of ST-segment depression at peak exercise was less ($p < 0.05$) during propranolol-verapamil than during propranolol-nifedipine treatment (Table I). During propranolol-verapamil treatment, 5 patients had angina during exercise testing, and they averaged 0.10 ± 0.08 mV of ST-segment depression. The remaining 11 patients in whom angina did not occur with this combination during exercise testing averaged 0.01 ± 0.02 mV of ST-segment depression ($p = 0.004$). With propranolol-nifedipine, the 7 patients who had angina during exercise testing averaged 0.09 ± 0.07 mV of ST-segment depression, whereas the other 9 patients in whom angina did not occur during exercise testing had 0.07 ± 0.07 mV of ST-segment depression (difference not significant).

Scintigraphic responses to supine bicycle exercise: At rest, the ventricular ejection fraction was higher ($p < 0.05$) during propranolol-nifedipine than during propranolol-verapamil treatment (Table I). However, the ejection fraction at rest during therapy with the 2 combinations was not significantly different from propranolol alone (Table I). At peak exercise, the ejection fraction during the 3 treatment periods was not significantly different (Table I). During the study, no patient had symptoms or signs of left ventricular failure. In 1 patient, the left ventricular ejection fraction at rest decreased from 0.44 with propranolol alone to 0.31 with propranolol-verapamil and 0.32 with propranolol-nifedipine.

Ambulatory electrocardiographic responses to therapy: With propranolol-verapamil, 6 patients had asymptomatic prolongation of the PR interval (0.21 to 0.25 second), 2 of whom had a prolonged PR interval with propranolol-nifedipine. No patient had second- or third-degree heart block during the study. The average heart rate with propranolol-verapamil was lower than

with propranolol alone and propranolol-nifedipine (Table I).

Discussion

When given alone, propranolol,[1–5] verapamil[6–9] and nifedipine[10,11] are effective in patients with angina of effort, and the combined administration of propranolol and either verapamil or nifedipine is usually beneficial in patients whose angina is severe. Although previous studies have shown that both propranolol-verapamil[12–14] and propranolol-nifedipine[15] are better than either agent alone in this patient population, none has compared these drug combinations with one another. The present randomized and double-blind assessment shows that in some ways, propranolol-verapamil is better than propranolol-nifedipine in treating patients with severe angina of effort. Although propranolol-verapamil and propranolol-nifedipine were of similar overall clinical efficacy in these patients, only propranolol-verapamil reduced anginal frequency and nitroglycerin usage in comparison with propranolol alone (Table I). Furthermore, propranolol-verapamil reduced the magnitude of exercise-induced ST-segment depression to a greater extent than propranolol-nifedipine (Table I). This greater antiischemic effect was limited to those in whom angina did not occur during exercise testing with combination therapy.

Antianginal mechanisms of propranolol-verapamil and propranolol-nifedipine: *Propranolol* reduces myocardial oxygen demands by decreasing the major determinants of myocardial oxygen consumption (heart rate, left ventricular contractility and systemic arterial pressure).[21–23] In addition, it may inhibit platelet aggregation[24] and increase the delivery of oxygen to tissues (such as the myocardium) by altering the affinity of hemoglobin for oxygen.[25] Propranolol does not cause coronary vasodilatation, and in patients with coronary arterial spasm, it may even induce vasoconstriction.[26] Like propranolol, *verapamil* diminishes myocardial oxygen demands (by reducing heart rate, left ventricular contractility and systemic arterial pressure),[27,28] but it also causes coronary vasodilatation and, therefore, may augment anterograde and retrograde coronary blood flow.[29] *Nifedipine* reduces myocardial oxygen demands by lowering systemic arterial pressure (and, as a result, left ventricular wall tension); in the doses given clinically, it does not exert a negative chronotropic or inotropic effect.[30] Like verapamil, nifedipine causes coronary vasodilatation and may improve coronary blood flow.

Because the β-adrenergic blocking drugs and calcium antagonists, in some ways, have complementary antianginal mechanisms, their combined administration may be beneficial in patients with severe angina of effort. For example, the increase in heart rate that often occurs with nifedipine may be prevented or at least blunted by concomitant propranolol, with a resultant decrease in myocardial oxygen demands. Alternatively, the propensity of propranolol to increase coronary vascular resistance in patients in whom coronary arterial spasm is operative may be prevented by the direct vasodilating influence of verapamil or nifedipine. Previous studies[12–15] have shown that each of the 2 drug combinations is superior to either agent alone in patients with angina of effort.

In comparison to propranolol alone, the increase in heart rate-systolic arterial pressure double product (an estimate of myocardial oxygen demand) caused by exercise was reduced by the 2 combinations by somewhat different mechanisms. The addition of verapamil to propranolol induced a decrease in heart rate and systolic arterial pressure, whereas the addition of nifedipine produced a decrease only in the latter. The patients who responded favorably to the addition of verapamil had a higher average heart rate with propranolol alone than those who failed to respond.

Although total exercise duration was not significantly prolonged during either combination, the majority of patients who received combination therapy stopped exercise because of fatigue and did not experience angina. Thus, the failure to observe an increase in exercise duration during combination therapy may reflect a close angina-to-fatigue relation in these patients. Furthermore, the mechanism by which propranolol-verapamil seemed to exert a greater antiischemic effect in patients who discontinued exercise without angina is not clear, but a propranolol-verapamil combination could conceivably reduce myocardial oxygen demands more effectively than a propranolol-nifedipine combination.

Adverse effects of combination therapy: Because propranolol and verapamil exert negative inotropic and chronotropic effects, their combined use may cause left ventricular failure, marked bradycardia or atrioventricular block. None of the 16 patients had symptoms or signs of left ventricular failure during propranolol-verapamil therapy, and the addition of verapamil did not reduce resting or peak exercise left ventricular ejection fraction in comparison with propranolol alone (Table I). Two patients (in whom the heart rates at rest during propranolol therapy alone were 51 and 54 beats/min, respectively) had weakness and lightheadedness during this combination and were noted to have a sinus bradycardia of 40 to 48 beats/min with intermittent junctional escape beats. In both, the dose of study medication was reduced from 3 to 2 times daily (and, in both, the study medication was verapamil). This change in verapamil dosage (to 240 mg/day) caused an alleviation of symptoms, and the heart rate increased to 50 to 55 beats/min. Asymptomatic first-degree atrioventricular block was noted in 6 patients during propranolol-verapamil therapy and in 2 during propranolol-nifedipine therapy, but more advanced heart block did not occur during the study. Although the incidence of adverse effects was low, patients with congestive heart failure or known conduction system disease were excluded from enrollment. Clearly, both propranolol-verapamil and propranolol-nifedipine should be administered with caution, especially in patients with 1 of these abnormalities. A propranolol-verapamil combination is of special concern, however, because it may produce a marked negative inotropic or chronotropic effect.

Strengths and weaknesses of the study: The present study has several strengths. First, it is a randomized, double-blind and crossover comparison of propranolol-verapamil and propranolol-nifedipine.

Second, the patients accurately represented those in whom combination β-blocking–calcium antagonist therapy is most often considered—namely, patients with severe, limiting angina of effort in whom substantial doses of propranolol are not totally effective. At the same time, the study has certain limitations. Each patient received a fixed dose of verapamil (360 mg/day) and nifedipine (60 mg/day), and therefore, we did not attempt to determine an optimal verapamil and nifedipine dose for each patient. The results of the study may have been different if the dose of each calcium antagonist had been individualized, but the frequency and severity of adverse effects probably would have increased.

Hemodynamic and Metabolic Effects of Diltiazem During Coronary Sinus Pacing with Particular Reference to Left Ventricular Ejection Fraction

MARTIN A. JOSEPHSON, MD, JAMES HOPKINS, BS, and BRAMAH N. SINGH, MD, Phil

To determine the systemic and coronary hemodynamic effects of diltiazem at rest and during pacing, 14 patients with stable angina pectoris undergoing coronary angiography were studied before and after 0.165 mg/kg (n = 7) and 0.25 mg/kg (n = 7) of intravenously administered diltiazem. Hemodynamic variables, metabolic measurements and left ventricular (LV) ejection fraction (EF) were obtained at rest and during coronary sinus (CS) pacing before and during diltiazem administration. Lactate production during control pacing turned into extraction after diltiazem ($p < 0.05$). At rest, systemic resistance was reduced by 21% ($p > 0.01$) and mean arterial pressure by 12% ($p < 0.01$); cardiac index increased from 2.4 ± 0.4 to 2.6 ± 0.4 liters/min/m^2 ($p < 0.01$), with no significant change in heart rate. The mean pulmonary artery pressure increased from 17 ± 2 to 19 ± 3 mm Hg ($p < 0.01$), but other hemodynamic variables were not affected. Diltiazem given during pacing reduced the mean aortic pressure (from 112 ± 15 to 104 ± 15 mm Hg, $p < 0.05$), but other hemodynamic variables were not affected significantly. LVEF decreased 16%, from 0.63 ± 0.9 to 0.53 ± 0.8 with CS pacing ($p < 0.01$); when the pacing was performed after diltiazem administration the 8% decrease in LVEF from 0.64 ± 0.09 to 0.59 ± 13 was less marked ($p < 0.01$). Diltiazem had no significant effect on LVEF at rest. The overall data suggest that the ischemic manifestations of CS pacing are attenuated by diltiazem in doses of the drug that exert no significant depressant effect on LV function in patients with coronary artery disease.

(Am J Cardiol 1985;55:286–290)

Numerous studies confirm the antiischemic efficacy of calcium antagonists.[1–4] However, these compounds differ significantly in their chemical structure and in their overall pharmacologic properties.[1,5,6] The dihydropyridines such as nifedipine exert no sympatholytic effects, whereas verapamil and diltiazem have variable, noncompetitive sympathetic inhibitory actions.[5] The peripheral vasodilator potencies of these 3 compounds also differ somewhat.[1,5,6] Thus, such differences in their pharmacologic properties may be relevant to their actions in ameliorating myocardial ischemia. Extensive data have now accumulated on the acute systemic and coronary hemodynamic effects of verapamil[7–9] and nifedipine[10–11] in patients with coronary artery disease in relation to pacing-induced myocardial ischemia. Few data are available on the effects of diltiazem, although its effects in exercise-induced angina[3,12] and in variant angina[13–15] are well established. The present study was performed to study the antiischemic mechanisms of diltiazem by defining its intravenous effects on systemic and coronary hemodynamics and left ventricular (LV) ejection fraction (EF) at rest and during pacing-induced myocardial ischemia in patients who underwent coronary angiography.

Methods

Patient group: Fifteen men with clinically stable coronary artery disease who underwent cardiac catheterization were studied. All patients had exercise treadmill tests which were positive for ischemia. Seven patients had a history of myocardial infarction. Patients with myocardial infarction less than 3 months old, hypertension, renal or hepatic disease or evidence of congestive heart failure were excluded. Beta-blocking drugs, calcium channel-blocking drugs or long-acting nitrate medications were withdrawn 48 hours before the study. Significant coronary stenoses, defined as a 50% or greater di-

ameter reduction in a major coronary artery, were present in 1 patient with 1-vessel, 5 with 2-vessel and 9 with 3-vessel coronary artery disease (Table I). LVEF ranged from 0.47 to 0.75 (mean 0.61).

Catheterization: A No. 7Fr thermodilution pacing catheter (Wilton-Webster) was positioned in the coronary sinus (CS) near the great cardiac vein. The catheter location was confirmed by contrast injection and positioned to avoid placing the thermistor adjacent to major veins entering the CS, to obtain stable baseline flow curves and to allow CS blood withdrawal. A balloon flotation catheter was positioned in the pulmonary artery and a pigtail catheter in the central aorta.

Measurements: Pressures were measured for a complete respiratory cycle using fluid-filled catheter systems and Bell and Howell pressure transducers. Zero pressure was set at midchest level. Cardiac output by thermodilution was measured in duplicate using an Instrumentation Laboratory 701 cardiac output system. CS flow was measured in 10 patients by thermodilution[16] using an injectate of 5% dextrose infused at a rate of 56 ml/min. Blood oxygen saturation was determined with an OSM 2 Hemoximeter (Radiometer). Blood lactate levels were measured by the method of Apstein et al.[17] The percent myocardial lactate extraction was calculated as: A-V/A × 100, where A and V = respective arterial and CS lactate concentrations. Standard electrocardiographic leads I, aVF and V_5 were recorded throughout the procedure. Permanent copies of data for subsequent analysis were stored on paper using a Honeywell Visicorder system. Derived hemodynamic variables were calculated as: Stroke work index in g-m/m^2 = SI × ($\overline{AP}$ − $\overline{PCW}$) × 0.0136, where SI = stroke index, $\overline{AP}$ = mean aortic pressure and $\overline{PCW}$ = mean pulmonary capillary wedge pressure. Systemic vascular resistance in dynes s cm^{-5} = 80 × ($\overline{AP}$ − $\overline{RA}$)/CO, where $\overline{RA}$ = mean right atrial pressure and CO = cardiac output. Pulmonary vascular resistance in dynes s cm^{-5} = 80 × ($\overline{PA}$ − $\overline{PCW}$)/CO, where $\overline{PA}$ = pulmonary artery pressure.

Radionuclide imaging: Radionuclide ventriculograms were obtained after in vivo blood pool labeling with 25 mCi of technetium-99m pertechnitate. This method was shown to be highly reproducible in our laboratory.[18] Data were processed by a single observer and LVEF was determined as:

$$\text{LVEF} = \frac{\text{(end-diastolic counts)} - \text{(end-systolic counts)}}{\text{(end-diastolic counts)} - \text{(background counts)}}$$

Study protocol: Baseline measurements were made at least 20 minutes after completion of the diagnostic cardiac catheterization. These included heart rate, right atrial, pulmonary artery, pulmonary capillary wedge and aortic pressures, cardiac output, CS blood flow, aortic and CS blood oxygen and lactate content. LVEF was measured simultaneously with pressure measurements. CS pacing was initiated at a rate 25% above the heart rate at rest and increased by 10 beats/min every 3 minutes until angina or atrioventricular (AV) block occurred. Four patients described only mild (1+ of 4) angina during pacing at a rate of 110 beats/min and the pacing rate was increased by 10 beats/min. After administration of diltiazem, these patients could be paced to only 110 beats/min. All of these measurements were repeated during pacing at submaximal (average, 15 beats/min less than maximal rate) and maximal pacing rates and again 10 minutes after cessation of pacing. Diltiazem, 0.25 mg/kg, was administered intravenously over 2 minutes, followed by a maintenance infusion of 0.0014 mg/kg/min for the duration of the study. Because of the development of second-degree AV block during pacing in 5 of 7 patients, which prevented pacing to the maximal rate before diltiazem, the dose of diltiazem was subsequently reduced to a bolus of 0.165 mg/kg given over 5 minutes and a 0.001-mg/kg/min infusion. At this dosage, AV block during pacing occurred in 2 of 7 patients. All variables were measured again during administration of diltiazem and diltiazem-pacing conditions. Comparisons made between pacing before and after diltiazem administration were made at the identical, although not the maximal rate, for patients in whom AV block developed after diltiazem administration.

Statistical analysis: Data are presented as mean ± standard deviation. Comparisons were made using 2-tailed paired Student t test and the limit of significance was set at $p < 0.05$.

TABLE I Age and Coronary Angiographic Findings Relative to Ventricular Function in the Study Group

Results

Hemodynamic effects: The effects of intravenous diltiazem on measured and derived hemodynamic variables are shown in Table II. At rest, diltiazem caused a 12% decrease in mean arterial pressure ($p < 0.01$) and a 21% decrease in systemic vascular resistance ($p < 0.01$) without a significant effect on heart rate. In the 7 patients who received the larger dose of diltiazem, the average decrease in mean arterial pressure was 15%, compared with a 10% decrease in the 7 patients who received the smaller dose. Cardiac index increased 8% ($p < 0.01$). Pulmonary artery pressure increased 12% ($p < 0.01$) and pulmonary capillary wedge pressure increased 11% ($p < 0.01$), but no significant changes were seen in right atrial pressure, stroke work index or pulmonary vascular resistance.

During pacing, chest pain developed in 10 patients. After diltiazem therapy, during pacing to identical heart rates (which produced chest pain before diltiazem), chest pain was either absent or subjectively reduced in 9 of these 10 patients. During pacing, diltiazem caused a decrease of 7% in the mean arterial pressure ($p < 0.05$) without significantly affecting other measured hemodynamic variables. The effect of diltiazem on systolic and diastolic pressures and heart rate × systolic blood pressure are shown in Figure 1. Diltiazem reduced systolic pressure 7% at rest ($p < 0.01$) and 6% during pacing ($p < 0.01$), and diastolic pressure 13% at rest ($p < 0.01$)

TABLE II Systemic Hemodynamic Effects of Intravenous Diltiazem at Rest and During Coronary Sinus Pacing

	Rest		Pacing	
	Control	Diltiazem	Control	Diltiazem
Heart rate (beats/min)	69 ± 10	68 ± 10	118 ± 12	118 ± 12
Mean right atrial pressure (mm Hg)	8 ± 3	8 ± 3	8 ± 4	8 ± 3
Mean pulmonary artery pressure (mm Hg)	17 ± 2	19 ± 3*	18 ± 4	19 ± 4
Mean pulmonary capillary wedge pressure (mm Hg)	9 ± 2	10 ± 3†	11 ± 4	11 ± 4
Aortic pressure (mm Hg)				
Mean	101 ± 11	89 ± 12*	112 ± 15	104 ± 15†
Systolic	139 ± 17	129 ± 20*	141 ± 19	132 ± 19†
Diastolic	77 ± 10	67 ± 10*	89 ± 12	84 ± 10†
Cardiac index (liters/min/m^2)	2.4 ± 0.4	2.6 ± 0.4*	2.8 ± 0.4	2.8 ± 0.4
Stroke index (ml/m^2)	35 ± 7	39 ± 6*	24 ± 4	24 ± 5
Systemic vascular resistance (dynes s cm^{-5})	1,546 ± 318	1,219 ± 254*	1,498 ± 328	1,362 ± 283
Pulmonary vascular resistance (dynes s cm^{-5})	123 ± 30	127 ± 36	102 ± 29	118 ± 39
Stroke work index (g-m/m^2)	43 ± 10	41 ± 8	32 ± 8	30 ± 9

* $p < 0.01$; † $p < 0.05$, diltiazem compared with control values.

and 6% during pacing ($p < 0.05$). The decreases in heart rate × blood pressure product of 9% at rest and 7% during pacing did not reach statistical significance, because the heart rate was not significantly affected by diltiazem and remained constant during pacing.

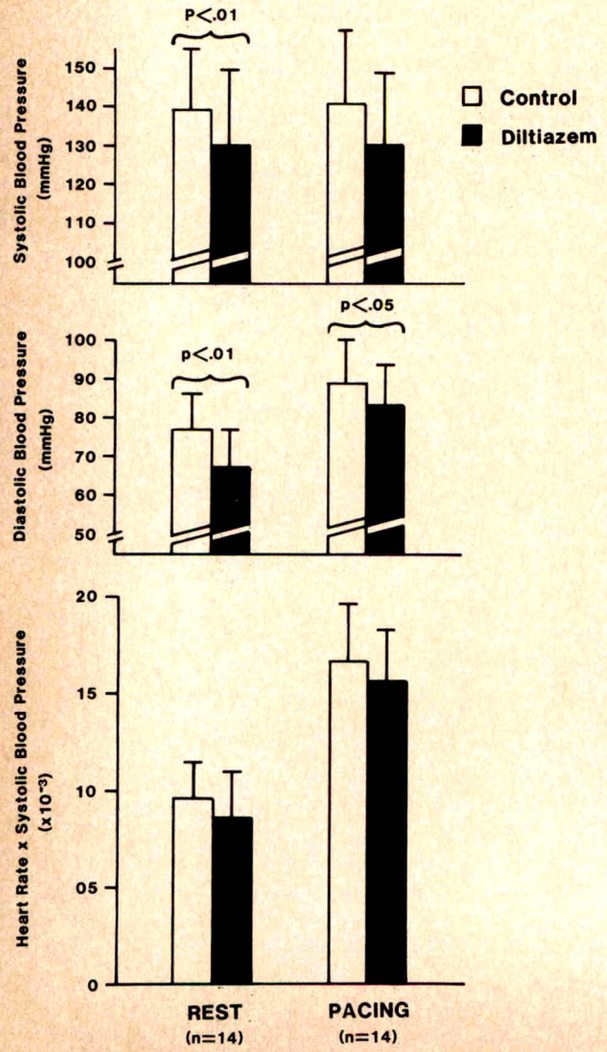

FIGURE 1. Effect of intravenous diltiazem on blood pressure and double product at rest and during coronary sinus pacing.

Effects of diltiazem on coronary flow and myocardial metabolism: The effects of diltiazem on coronary hemodynamics are listed in Table III. Pacing resulted in a 51% increase in CS flow and a 54% increase in myocardial oxygen consumption. There was no significant change in either of these parameters at rest or during pacing after diltiazem administration, although the measured myocardial oxygen consumption during pacing was reduced 11% (difference not significant). A significant increase in myocardial lactate extraction ($p < 0.05$) was seen after administration of diltiazem during pacing.

Effects of diltiazem on left ventricular ejection fraction: Figure 2 shows the effect of pacing on LVEF. The mean LVEF of 0.63 decreased 16% to 0.53 ($p < 0.01$) during pacing. Diltiazem had no effect on LVEF at rest (Fig. 2B). At rest after diltiazem, the LVEF was 0.64, not significantly different from its respective control value (0.63). During pacing after diltiazem administration, a significant 8% decrease ($p < 0.01$) in LVEF to 0.59 occurred, which was significantly higher than that of 0.53 during pacing at an identical mean heart rate before diltiazem administration ($p < 0.01$).

No significant adverse effects attributable to the administration of diltiazem developed during the study; however, AV nodal periodicity developed during CS pacing in 7 patients.

Discussion

This study demonstrates the beneficial effect of intravenous diltiazem in ameliorating the decrease in LVEF and other manifestations of ischemia induced by CS pacing in patients with coronary artery disease. LVEF is an objective and highly reproducible method for evaluating the effects of ischemia on ventricular function.[18,19] In the absence of coronary artery disease LVEF increases during atrial pacing.[20] No patient in our study had valvular or primary myocardial disease. Thus, the 16% reduction in LVEF after pacing in our patients must have been due to the development of myocardial ischemia. Other manifestations of pacing-induced ischemia include chest pain, changes in LV filling pressure, ST-segment changes and lactate production. Chest pain has been shown to be a nonspecific symptom with pacing, occurring with similar frequency in normal subjects and patients with coronary disease; the other

parameters are more specific but quite insensitive as markers of ischemia when atrial pacing rates not exceeding 140 beats/min are used.[20] In our study, pacing rates higher than 140 beats/min were precluded by AV nodal conduction. The effect of diltiazem on LVEF occurred coincident with a 7% decrease (difference not significant) in heart rate × blood pressure product. Such an effect might be expected to decrease myocardial oxygen demands and reduce the ischemic ventricular dysfunction.

Although a reduction in myocardial oxygen demand is believed to be the predominant mechanism by which diltiazem[12] and other calcium antagonists[9,11,21,22] act in ischemia induced by pacing or exercise, other contributing mechanisms cannot be discounted. For example, in the study by Petru et al,[12] oral diltiazem did not affect heart rate × blood pressure product at peak exercise. Although there was no difference in the gross determinants of myocardial oxygen consumption, LVEF at peak exercise was 18% higher (0.52 vs 0.44, $p < 0.01$) during diltiazem therapy. Additionally, there was no difference in either end-systolic or end-diastolic volumes. Thus, other potential mechanisms of action of diltiazem, such as improved myocardial perfusion and reduction in oxygen demand due to improved ventricular compliance, must be considered.

Diltiazem has improved myocardial blood flow to ischemic regions in a variety of animal models.[23,24] CS flow was unchanged after diltiazem therapy in our study when myocardial oxygen demands were decreased, although diltiazem decreased coronary resistance 18% at rest and 9% during pacing. Data from other studies on coronary flow with calcium antagonist therapy have been variable. For example, nifedipine has been shown to increase CS flow relative to myocardial oxygen consumption.[11,25] Studies with verapamil have shown either no change[26] or a decrease[27] in CS flow. Small changes in regional myocardial flow that might be significant may not be detectable in the more global measurement of CS flow assessed by thermodilution. Verapamil decreases the cross-sectional area of stenosis by 13%[26]; similar effects have been shown with diltiazem,[28]

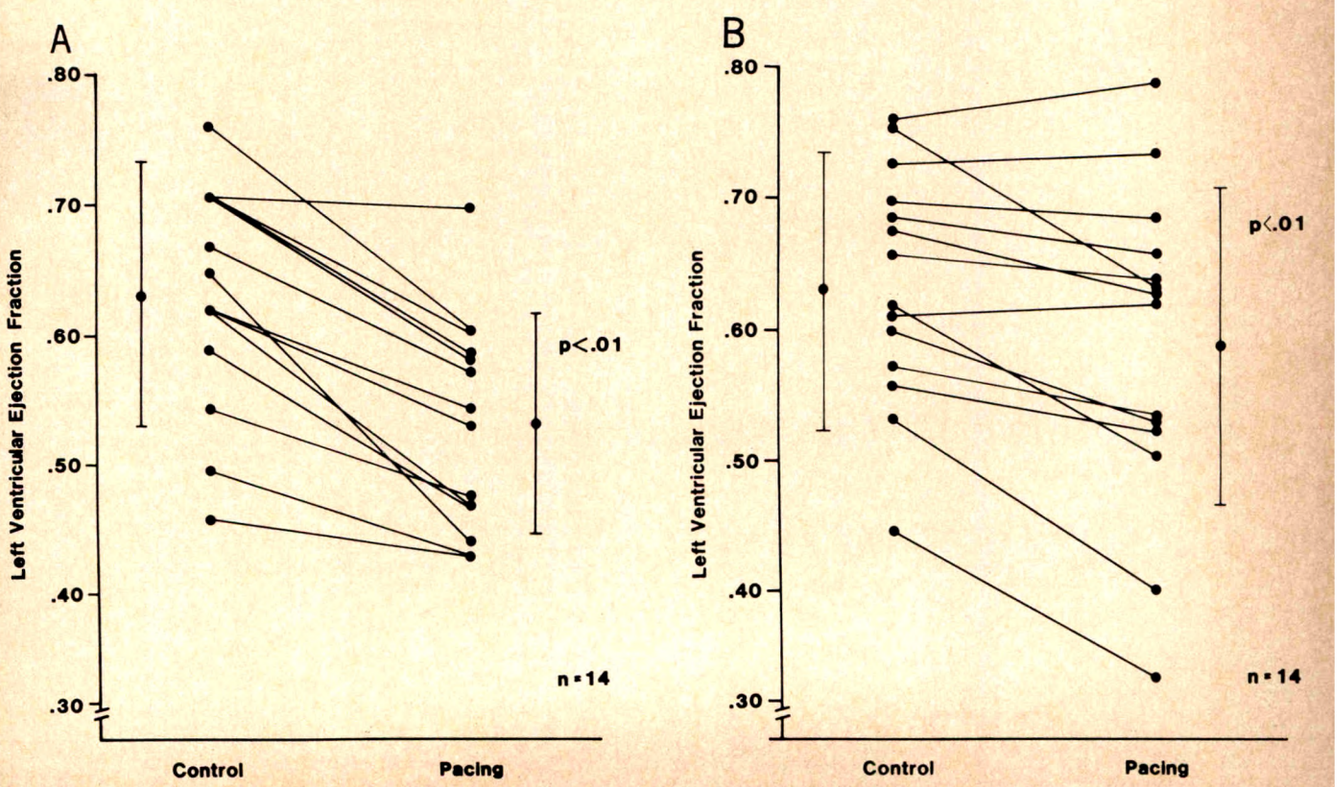

FIGURE 2. A, radionuclide left ventricular ejection fraction at rest and during coronary sinus pacing. **B,** effect of diltiazem on left ventricular ejection fraction at rest and during coronary sinus pacing.

suggesting an additional mechanism through an improvement in myocardial perfusion. Furthermore, from analogy to the overall actions of verapamil,[29] a component of the antianginal action of diltiazem may be attributable to its favorable effect on the diastolic properties of the ischemic myocardium. However, this presumed action of the drug requires investigational verification.

Our data are of interest from the standpoint of the hemodynamic effects of diltiazem in patients with coronary artery disease. In doses between 0.165 and 0.25 mg/kg given intravenously, diltiazem produced somewhat smaller reductions in systemic vascular resistance than either verapamil[1,9] or nifedipine[10,11] in patients with relatively normal EFs. The small increase in the induced pulmonary capillary wedge pressure after diltiazem probably results from a reduction in myocardial contractility. Because cardiac and stroke volume indexes increased and LVEF was unchanged after diltiazem therapy, the depressant effect of diltiazem on myocardial contractility is offset by the peripheral effects of this drug. These changes are more akin to those induced by verapamil than by nifedipine, which is the most potent peripheral vasodilator of the 3 compounds and exerts the most striking reflex effects on contractility. This finding appears to be reflected particularly in the changes induced by 3 compounds in LVEF. For example, verapamil usually produces no change in LVEF,[21] and diltiazem produces either no change or a slight increase as found in our studies with significant increases that occurred when sublingual or single oral doses of nifedipine were given.[30] The overall comparative data indicate the varying propensity of the 3 compounds in affecting myocardial contractility. However, our data do not exclude the possibility that, as with verapamil,[31] diltiazem may produce depression of ventricular performance in patients with imparied ventricular function especially at large doses.

Familial Aggregation and Early Expression of Hyperapobetalipoproteinemia

ALLAN SNIDERMAN, MD, BABIE TENG, MSc, JACQUES GENEST, MD, KATHERINE CIANFLONE, BSc, SHOLOM WACHOLDER, PhD, and PETER KWITEROVICH Jr., MD

Family history is an important predictor of coronary risk. However, this relation, in large part, is not explained by the known risk factors such as systemic hypertension or hyperlipidemia. In the present study, plasma lipid, lipoprotein lipid, and plasma low-density lipoprotein (LDL) apoB levels were measured in 66 offspring (myocardial infarction [MI] offspring) of 24 families in which an index parent had premature coronary artery disease and hyperapobetalipoproteinemia. These results were compared to those obtained in 207 control children and young adults. Univariate analysis revealed that plasma LDL apoB and all other lipid and lipoprotein levels except high-density lipoprotein cholesterol were significantly higher in the MI offspring. Multivariate analysis showed plasma LDL apoB and LDL cholesterol best differentiated the MI offspring from control children and young adults. Of the 66 children, 22 had hyperapobetalipoproteinemia, of whom only 7 had clearly abnormal LDL cholesterol or plasma triglyceride levels. Thus, a substantial portion of children born to a parent with premature coronary artery disease and hyperapobetalipoproteinemia have the same disorder of lipoprotein metabolism.

(Am J Cardiol 1985;55:291–295)

There is little doubt that the plasma lipoproteins significantly influence the risk of coronary artery disease (CAD). However, this relation is complex with, on the one hand, risk increasing as low-density lipoprotein (LDL) levels increase, but on the other, decreasing as high-density lipoprotein (HDL) levels increase.[1,2] To this long-standing epidemiologic network of evidence can now be added the recent demonstration that appropriate dietary and pharmacologic therapy significantly decreases the incidence of CAD death rate and myocardial infarction (MI) in patients with type II hyperlipoproteinemia.[3]

Even though most patients with premature CAD have LDL cholesterol levels within the normal range, this does not mean their LDL is always normal. LDL are complex particles with the principal lipid, cholesterol ester, sequestered in a core surrounded by a surface layer made up of cholesterol, phospholipid and the major protein in LDL—apoB.[4] Until recently, the plasma concentration of LDL was usually expressed only by its cholesterol content. But this practice provides incomplete information. For example, we observed that although most patients with premature CAD have normal LDL cholesterol levels, many have elevated LDL apoB values—a combination we called hyperapobetalipoproteinemia.[5] And indeed, several studies indicate that apoprotein levels do identify patients at high risk of CAD more clearly than do lipid levels.[5–15]

Although lipoprotein cholesterol levels clearly modulate risk for individuals another body of evidence points to the aggregation of CAD within families, and this phenomenon apparently cannot be completely explained by the factors known to affect coronary risk.[16–18] Therefore the purpose of this study was to examine the plasma lipids, lipoprotein lipids, and plasma LDL apoB levels in children of families where 1 parent had both premature CAD and hyperapobetalipoproteinemia. These data were then compared with those from 3 unrelated control groups of children and young adults to determine whether familial aggregation

TABLE I Plasma Total Lipid, Lipoprotein Cholesterol and Plasma Low-Density Lipoprotein ApoB Levels in Offspring of Patients with Hyperapobetalipoproteinemia and Myocardial Infarction and Unrelated Control Groups

	MI Offspring	C 1+2+3	C1	C2	C3
TC (mg/dl)	174 ± 34†	164 ± 27	172 ± 19	150 ± 31	164 ± 29
Tg (mg/dl)	103 ± 58‡	81 ± 32	83 ± 21	87 ± 44	78 ± 32
LDL C (mg/dl)	103 ± 33*	93 ± 27		92 ± 30	93 ± 27
HDL C (mg/dl)	51 ± 13	52 ± 11		40 ± 8	56 ± 9
LDL apoB (mg/dl)	110 ± 36‡	82 ± 18	80 ± 16	73 ± 24	87 ± 14

* $p < 0.05$; † $p < 0.01$; ‡ $p < 0.0001$.
C1, C2, C3 = control groups 1, 2 and 3; HDL C = high-density lipoprotein cholesterol; LDL apoB = low-density lipoprotein apoB; LDL C = LDL cholesterol; MI offspring = children of affected parents; TC = total plasma cholesterol; Tg = total plasma triglyceride.

of hyperapobetalipoproteinemia is present within the offspring of the index cases.

Methods

Study groups: *Children of affected parents:* The children of affected parents (MI offspring) consisted of children in 24 families in which 1 parent had both a documented MI before the age of 55 years and hyperapobetalipoproteinemia. All index parents but one were male. Their average age was 48 ± 8 years (mean ± standard deviation) and all had hyperapobetalipoproteinemia, that is, the plasma LDL apoB level was at least 120 mg/dl and the LDL cholesterol was at least 200 mg/dl. Fasting plasma samples were obtained from 66 children and young adults in these families, representing 84% of the total number of offspring. The average age of those studied was 17 ± 7 years (range 3 to 31). Thirty-one were male and 35 were female subjects.

Control groups: Three unrelated groups of children and young adults were studied. Group C1 consisted of 62 healthy Montreal children from whom plasma samples were obtained at a routine health examination. Their average age was 11.6 ± 8 years (range 4 to 23). Twenty-eight subjects were male and 34 were female. Group C2 consisted of 40 children in grade 10, all males, sampled as part of a larger project to determine community lipid and lipoprotein values. These children live in a small Pennsylvania city and their age was 16 ± 1 years. Group C3 consisted of 105 medical students at The Johns Hopkins University with an average age of 20.8 ± 1.5 years (range 19 to 30 years). Ninety subjects were male and 15 were female.

Laboratory methods: After a fast of 12 hours, blood samples were obtained in tubes containing EDTA (1 mg/ml) and plasma then separated by centrifugation. Plasma total cholesterol and triglyceride were measured enzymatically. HDL cholesterol was determined in the supernatant after precipitation of the apoB containing lipoproteins by heparin and manganese chloride.[19] In the MI offspring, LDL was isolated by preparative ultracentrifugation between density 1.006 to 1.063 g/ml.[5] That is, the density <1.006 lipoproteins were first removed and then LDL isolated after a second ultracentrifugation at density 1.063 g/ml. In groups C2 and C3, LDL cholesterol was determined using the methods of the Lipid Research Clinic.[19] Plasma LDL apoB was measured in all groups by radial immunodiffusion.[20] In groups MI, C1 and C3, this was done at the Royal Victoria Hospital laboratory using a 1.5% agarose gel read at 18 hours. In groups C2, radial immunodiffusion was performed at The Johns Hopkins laboratory using a 2% agarose gel read at 72 hours. The measurements in the 2 techniques agree closely (r = 0.96).

Normal limits for plasma lipids and lipoprotein lipids were based on the Lipid Research Clinics Prevalence Study.[21] The upper limit, based on our previous studies in adults for plasma LDL apoB, was fixed at 120 mg/dl.

Groups were compared initially with *t* tests with the data then adjusted for age and sex effects by analysis of covariance. Multiple logistic regression was then employed to search for the most informative parameters.[22]

Results

The means and standard deviations for all measurements are summarized in Table I. Each of the 3 control groups is listed separately and these values are averaged to provide an overall mean for the control group. The values for the MI offspring were then compared with those of the overall control group.

First, a univariate comparison was carried out using an unpaired *t* test. This revealed that plasma total cholesterol, total triglyceride, and plasma LDL apoB levels were all significantly higher in the MI offspring than in the control group. By contrast, the mean HDL cholesterol levels did not differ significantly between these 2 groups. The influence of age and sex was next considered, and these factors were determined in the control group with all data then adjusted by analysis of covariance. This altered the absolute differences between the groups only slightly and the differences noted above remained just as significant.

Multivariate analysis was then undertaken by multiple logistic regression: plasma LDL apoB was the parameter selected first as significant with LDL cholesterol identified next. Addition of the 3 other lipid variables did not substantially improve the fit. Thus, multivariate analysis identified plasma LDL apoB and then LDL cholesterol as the measurements that permit best separation of the MI offspring and control group.

These differences can also be appreciated by comparing the difference between the means of the control and MI offspring of a given measurement as a fraction of the control standard deviation. Thus, the mean for plasma total cholesterol in the MI offspring differs from the mean in the control offspring by much less than 1 standard deviation. This is also the case for LDL cholesterol, while the difference is only a bit larger (0.62) for triglyceride. By contrast, there is a much larger difference between the 2 groups for plasma LDL apoB. In this instance, the difference is 1.5 times the control standard deviation. So that the magnitude of difference

between the 2 groups for LDL cholesterol and LDL apoB can readily be seen, histograms for these 2 variables are shown in Figure 1.

Table II lists the persons in the MI offspring with elevated plasma LDL apoB. The youngest was 4 years old, a boy, and the oldest was 33 years old, a woman. Of these 22, 4 had LDL cholesterol values above the 95th percentile for age and sex and, thus, would be recognized as abnormal; 2 others were just at this limit. One young adult with an increased LDL cholesterol also had an elevated plasma triglyceride level, whereas 3 others had increased plasma triglyceride, but normal LDL cholesterol levels; 2 had plasma triglyceride levels at the 95th percentile. Thus, only 7 of the 22 had clearly abnormal lipid levels; the rest, were it not for plasma LDL apoB, would have been conventionally characterized as normal.

Discussion

This study examines children and young adults in families where a parent had both suffered a premature MI and had hyperapobetalipoproteinemia. Many of the offspring also have hyperapobetalipoproteinemia; that is, they had elevated LDL apoB levels in the face of a normal LDL cholesterol. Only a few had elevated LDL cholesterol or plasma triglyceride levels, and thus measurement of plasma and lipoprotein lipid variables did not clearly identify many persons within the MI offspring as being different from the 3 control groups of children and young adults. By contrast, measurement of plasma LDL apoB differentiated the primary study group from the 3 control groups, also identified the few children with elevated LDL cholesterol, but more importantly, identified the larger number with hyperapobetalipoproteinemia.

Familial aggregation of CAD has been demonstrated repeatedly. The Western Collaborative Study[23] revealed a significant link between the history of CAD and parental history of CAD; while Slack and Evans showed a several-fold excess mortality in the relatives of index cases with CAD compared to the normal population.[24]

Nevertheless, the connection between familial aggregation of CAD and familial aggregation of lipids is clearly imperfect.[16–18] More recently, however, the relation of apoproteins to risk of CAD has been examined. Although most patients with premature CAD are normocholesterolemic,[5,25] there is now considerable agreement that, on average, apoB levels are higher and $apoA_1$ (the major apoprotein in HDL) levels lower in patients with CAD than in those without disease.[5–15] Nevertheless, all such studies on the relation of apoprotein levels to atherosclerosis have been cross-sectional since the presence or absence of disease was related to concurrent lipid and apoprotein levels. Therefore, the apoprotein abnormalities observed may have been simply a consequence, rather than a precursor, of vascular disease. The present data indicates that hyperapobetalipoproteinemia is expressed in families with premature CAD long before the usual age when clinical symptoms begin, and therefore contributes strongly to the hypothesis that this metabolic disorder may well be important in the pathogenesis of CAD. Our hypothesis is further strengthened by the results of Kukita et al,[26] who reported that apoB levels in first-degree adult relatives of patients with angiographically diagnosed CAD were significantly higher than those in age- and sex-matched control subjects.[26]

Even though a child as young as 4 years was affected, most of those with hyperapobetalipoproteinemia were beyond puberty, and thus it is possible that this disorder is not fully expressed until young adulthood. In the present study, the control groups were chosen not only to bracket the age range in the primary study group, but

also to be from different geographic sites so as to make them more likely a representative of Canadian and American norms at these ages.

The physiochemical basis for the disproportionate increase in LDL apoB compared to LDL cholesterol characteristic of hyperapobetalipoproteinemia is now clear. Even in normal persons, LDLs are heterogeneous particles differing in size and cholesterol content but with a constant amount of protein per particle. The larger LDL particles are thus less dense and contain more core cholesterol, but relatively less protein; the converse is the case for smaller LDL particles. In hyperapobetalipoproteinemia, the number of LDL particles is above normal, but the cholesterol level is not proportionately elevated because most of the particles are smaller and denser, depleted in cholesterol ester and relatively enriched in protein.[27]

Although in no way established, it is possible that the familial aggregation of hyperapobetalipoproteinemia evident in the present study may to an important degree, be genetic, and this, obviously, is an important hypothesis to pursue. Of the lipoprotein disorders associated with premature CAD, familial hypercholestrolemia is best characterized, but accounts for only a small portion, about 5%, of the premature CAD seen clinically. Another disorder, familial combined hyperlipidemia, first described in 1973, has been found in a higher proportion, from 10 to 20%, of patients with premature CAD.[28] Familial combined hyperlipidemia is characterized by the presence of multiple lipoprotein phenotypes within a family, but it has now been shown that there is a common denominator linking these various phenotypes—an elevated total plasma apoB.[29] Thus, there may be considerable, although not complete, homology between hyperapobetalipoproteinemia and familial combined hyperlipidemia.[30]

Continuous Positive Airway Pressure by Face Mask in Acute Cardiogenic Pulmonary Edema

JUKKA RÄSÄNEN, MD, JUHANI HEIKKILÄ, MD, JOHN DOWNS, MD, PERTTI NIKKI, MD, IRMA VÄISÄNEN, MD, and ANNE VIITANEN, MD

The therapeutic efficacy of continuous positive airway pressure (CPAP) administered by face mask was studied in 40 patients with acute cardiogenic pulmonary edema and respiratory failure. Arterial blood gas values and pH, systemic arterial pressure, heart rate and respiratory rate were measured during administration of 30% oxygen with a high-flow face mask apparatus at ambient airway pressure. Twenty patients were then randomly chosen to continue ambient airway pressure breathing and 20 received 10 cm H_2O of CPAP. The measurements were repeated 10, 60 and 180 minutes after therapy was initiated. During the first 10 minutes of CPAP treatment, arterial blood oxygen partial pressure increased 8 ± 9 mm Hg (mean ± 1 standard deviation), ($p < 0.01$) and respiratory rate decreased 5 ± 5 breaths/min ($p < 0.001$). Systolic arterial pressure decreased 12 ± 21 mm Hg ($p < 0.05$), and heart rate by 10 ± 11 beats/min ($p < 0.001$). A decrease in respiratory rate by 2 ± 5 breaths/min ($p < 0.05$) was the only change that occurred in the control group. The improvement in arterial blood oxygenation persisted throughout the investigation period ($p < 0.05$). Thirteen patients (65%) in the control group and 7 patients (35%) in the CPAP group met our criteria for treatment failure during the study ($p = 0.068$). Thus, CPAP administered by face mask improves gas exchange, decreases respiratory work, unloads circulatory stress, and may reduce the need for ventilator treatment in acute cardiogenic pulmonary edema.

(Am J Cardiol 1985;55:296–300)

Continuous positive airway pressure (CPAP) is known to improve arterial blood oxygenation in acute respiratory failure of both cardiac[1–3] and noncardiac[4] origin. It also may decrease the work of spontaneous breathing by improving lung mechanics.[3,5,6] CPAP is usually combined with mechanical ventilation and applied to the patient through an endotracheal tube. However, the complications of endotracheal intubation and ventilator treatment[7] may be particularly hazardous in patients with heart disease and acute pulmonary edema. Elevated airway pressure also can be administered with a tight-fitting face mask to patients who do not require endotracheal intubation for mechanical ventilation or for airway support.[8,9] The use of a face mask for CPAP in cardiogenic pulmonary edema has been described previously,[1,3] but its efficacy has not been tested prospectively. This investigation determines whether cardiopulmonary function could be improved and ventilator treatment avoided by applying CPAP with a mask to patients with acute cardiogenic pulmonary edema.

Methods

Patients: The study group consisted of 40 patients with respiratory failure and clinical and radiologic evidence of acute, alveolar pulmonary edema of cardiac origin. The diagnostic criteria of respiratory failure were dyspnea, signs of increased respiratory work such as intercostal and suprasternal retractions or use of accessory respiratory muscles during inspiration, a respiratory rate of more than 25 breaths/min or arterial blood oxygen partial pressure (PaO_2) to inspired oxygen concentration ratio of less than 200. We excluded patients who were unresponsive to speech, those unable to maintain patent airway, and those who had signs of lung infection, evidence of pulmonary embolism, or chronic lung disease with carbon dioxide retention at rest. Relevant data concerning clinical features and medical treatment are listed in Table I. All patients had severe heart failure primarily after acute myocardial infarction (n = 19) or acute exacerbation of chronic left ventricular dysfunction (n = 19). The study was started immediately after the clinical diagnosis had been made.

Continuous positive airway pressure device: A high-flow, venturi-powered face mask apparatus (Vital Signs)

similar to one described earlier[10] was used for spontaneous breathing in all patients. CPAP was achieved by attaching a threshold resistor valve to the mask. The opening pressure of the valve was checked before use. When the valve was not in place, the airway pressure was ambient. The venturi was connected to a high-pressure oxygen source with its entrainment orifice open to room air. Because the entrained air was not enriched with oxygen, the inspired oxygen concentration was 28 to 30%, depending on the entrainment ratio of the particular venturi in use. Room air entrainment assured that the inspired oxygen concentration was unaffected by changes in flow rate and airway pressure. Therefore, it remained constant throughout the study. The flow rate was adjusted to keep the exhalation valve open throughout the respiratory cycle, thus ensuring a nearly constant airway pressure.

Experimental protocol: One of the investigators or the anesthesiologist on call in the intensive care unit evaluated patients for potential inclusion in the study, supervised the respiratory therapy and recorded the results of the measurements. After initiation of the investigation, all patients breathed with the face mask apparatus with an ambient airway pressure for 5 minutes. Then, baseline heart rate, respiratory rate, blood pressure and results of arterial blood analyses were recorded. Patients then were randomly assigned to 1 of 2 groups by opening 1 of 40 sealed envelopes containing instructions for the use of either ambient airway pressure (control group, n = 20) or 10 cm H_2O CPAP (CPAP group, n = 20). Cardiopulmonary measurements were repeated after 10, 60 and 180 minutes of group specific therapy. Heparinized arterial blood was analyzed for pH, Pa_{O_2}, and carbon dioxide partial pressure (Pa_{CO_2}) within 5 minutes of sampling (ABL-2, Radiometer). The study was interrupted after a 10-minute trial of the assigned treatment if any of the following criteria were met: Pa_{O_2} <50 mm Hg, Pa_{CO_2} >55 mm Hg or respiratory rate >35 breaths/min. The time of the study then was recorded and the patient classified as a failure of the assigned treatment. Subsequent respiratory therapy in these patients was determined by the physician in charge. Loss of consciousness or airway obstruction were indications for endotracheal intubation and ventilatory assistance at any time. Medical treatment of pulmonary edema was not restricted. Airway pressure and inspired oxygen concentration were not changed during the data collection period. Need for ventilator treatment after the study and final outcome were determined from medical records after patients left the hospital.

The study protocol was approved by the Committees on Ethics of the Department of Anesthesiology and of the First Department of Medicine at Helsinki University Central Hospital.

Data analysis: Baseline cardiopulmonary data of the groups were compared using the Student *t* test for means of independent samples. The 10-minute and 3-hour cardiopulmonary responses to therapy were analyzed separately. Data from all patients were included when the response to the first 10 minutes of therapy was analyzed. The Student *t* test for paired observations was used to detect significant differences within groups. Responses of the groups to treatment were compared using the Student *t* test for means of independent samples. Changes over the entire study period were analyzed only if patients maintained spontaneous respiration throughout the 3-hour study. A 1-way repeated measures analysis of variance was then used to detect changes within the groups. Responses of the groups to treatment were compared with a 2-way repeated measures analysis of variance. The percentage of patients that maintained spontaneous breathing during the study was plotted as a function of time in both groups using the life-table method. The curves so constructed were compared with the Mantel-Cox test. The differences in mortality and in the frequency of ventilator treatment were compared with the Fisher's exact test.

TABLE I Clinical Features and Medical Treatment of the Patient Series*

	Control (n = 20)	CPAP (n = 20)
Age (yr)	73 ± 9	74 ± 9
Men/women	7/13	6/14
Underlying cause of pulmonary edema

Nitroglycerin (no. of pts)	4	1
Nitroprusside (no. of pts)	3	3
Digitalis (no. of pts)	6	8
Dopamine (no. of pts)	4	4
Dobutamine (no. of pts)	0	1
Urine output (ml/3 hr) (mean ± SD)	918 ± 461	766 ± 575

* Differences not statistically significant.
† Cumulative doses of furosemide, morphine and diazepam were calculated starting 6 hours before and ending 3 hours after randomization. The use of inotropic drugs or vasodilators was taken into account if these drugs were given within 3 hours of randomization.
CPAP = continuous positive airway pressure; SD = standard deviation.

Results

The control and CPAP groups were found to be comparable with regard to age, gender, underlying cause of pulmonary edema, medical treatment and cardiothoracic ratio (Table I). All patients maintained spontaneous respiration for the first 10 minutes of the study. Seven patients in the control group and 13 patients in the CPAP group completed the investigation. Twenty patients met our criteria for failure of assigned treatment. No technical problems were associated with either treatment, nor were there any complications related to the face mask such as nasal bridge pain, gastric dilatation or aspiration.

Pulmonary function: Upon inclusion in the study, all patients had moderate to severe respiratory failure. The respiratory rate ranged from 11 to 47 breaths/min, Pa_{O_2} from 31 to 74 mm Hg and Pa_{CO_2} from 24 to 76 mm Hg (Table II).

The respiratory rate of patients in the control group decreased slightly ($p < 0.05$) during the first 10 minutes of treatment with an ambient airway pressure. The arterial P_{O_2}, P_{CO_2} and pH remained unchanged. When CPAP was applied, Pa_{O_2} increased 8 ± 9 mm Hg ($p < 0.01$). Simultaneously, the respiratory rate decreased ($p < 0.001$) as did the Pa_{CO_2} ($p < 0.01$). Clinically, the use of CPAP frequently improved the patient's breathing pattern, decreased intercostal and suprasternal retractions, and relieved subjective respiratory distress. The response of arterial blood oxygenation to the first 10 minutes of therapy was significantly different in the 2 groups ($p < 0.001$). This difference persisted over the entire 3-hour investigation period ($p < 0.05$) (Fig. 1). The

All values are expressed as mean ± standard deviation.
CPAP = continuous positive airway pressure.

respiratory rate decreased progressively and the arterial pH increased even though Pa_{CO_2} remained unchanged in both groups (Table III).

Cardiovascular function: Baseline systolic arterial pressure ranged from 70 to 220 mm Hg and heart rate from 64 to 155 beats/min. Patients who received CPAP had a slightly lower systolic blood pressure and higher heart rate than those in the control group (difference not significant [NS]) (Table II).

No circulatory changes were noted in the control group during the first 10 minutes of therapy. The use of CPAP was associated with a decrease in heart rate ($p < 0.001$), blood pressure ($p < 0.05$) and rate-pressure product ($p < 0.01$). The changes in heart rate and rate-pressure product differed significantly between the 2 groups ($p < 0.01$). A decrease in an initially low systolic blood pressure (110 mm Hg or lower) was seen on 1 of 4 occasions in the control group and on 3 of 8 occasions in the CPAP group (NS). During the 3-hour follow-up, arterial pressure decreased significantly in both groups, but the heart rate and the rate-pressure product decreased only in the patients who received CPAP (Table III).

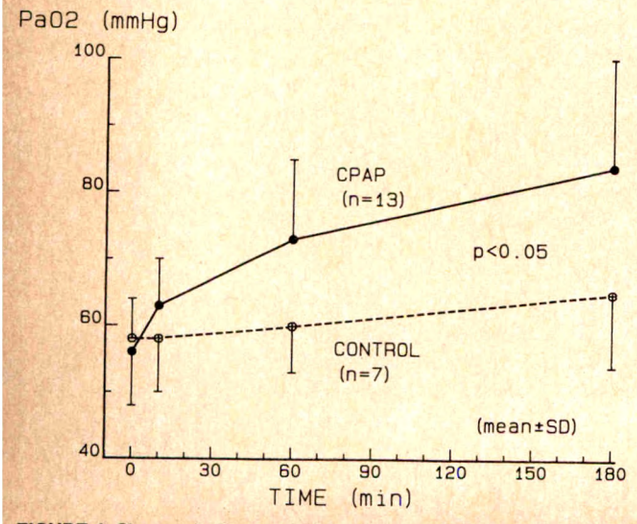

FIGURE 1. Changes in the arterial blood oxygen partial pressure (Pa_{O_2}) over the 3-hour observation period in 7 patients breathing with an ambient airway pressure and in 13 patients receiving 10 cm H_2O continuous positive airway pressure (CPAP). SD = standard deviation.

Clinical course: On inclusion in the study, 12 patients in the control group and 10 patients in the CPAP group met the criteria for treatment failure. After 10 minutes of group specific therapy, 3 of the 12 patients who breathed with an ambient airway pressure and 5 of the 10 who received CPAP improved and remained in the study. By the end of the 3-hour observation period, the study had been interrupted in 13 patients in the control group and in 7 patients in the CPAP group, usually because of arterial hypoxemia (Table IV). The comparison of treatment failure frequency data in the 2 groups revealed differences of borderline significance ($p = 0.068$) (Fig. 2). Three patients in each group were not mechanically ventilated despite failure of the assigned treatment. Two patients in each group were intubated after the study had been completed, 1 because of reinfarction and pulmonary edema, 2 because of irreversible cardiogenic shock and 1 during cardiopulmonary resuscitation. The differences in the hospital mortality and in the total frequency of ventilator treatment between groups were not statistically significant.

Discussion

Respiratory distress with associated hypertension and tachycardia is a major threat to the ischemic myocardium of a patient having acute cardiogenic pulmonary edema. Several theoretical aspects favor the use of CPAP as a primary method of providing respiratory support to these patients. The increase in transpulmonary pressure and functional residual capacity both reduces hypoxemia by decreasing intrapulmonary shunt and relieves respiratory work by improving lung compliance.

CPAP = continuous positive airway pressure.

In the present study, 10 cm H_2O of CPAP applied with a face mask improved arterial blood oxygenation. A spontaneous improvement in gas exchange was very slow to occur in patients in the control group who breathed the same oxygen concentration with the same apparatus, but with an ambient airway pressure. A significant difference between the physiologic responses of the patients in the groups was evident throughout the study.

Several investigators mention a reduction of respiratory work as an advantage of CPAP therapy[3,5,6] although no definite proof of such an effect exists. Because we did not measure transpulmonary pressure change or tidal volume, we cannot directly assure that respiratory work decreased during either treatment. However, a decreased respiratory rate with subjectively determined less labored breathing, yet with a lower Pa_{CO_2} in the CPAP group is indirect objective evidence of decreased work of breathing.

Relief of respiratory distress was associated with significant cardiovascular effects in the patients who received CPAP. Arterial pressure, heart rate and rate-pressure product decreased significantly and persistently within 10 minutes, but existing hypotension was not aggravated. A similar but more gradual effect was noted during the 3-hour follow-up of patients in the control group as well. The hemodynamic response to CPAP indicates relief from the circulatory stress mediated by sympathoadrenergic drive in acute cardiogenic pulmonary edema.[11] The absence of adverse circulatory effects of CPAP is in accordance with findings in recent studies suggesting that elevated intrathoracic pressure does not impair the function of a failing left ventricle and in fact may assist it.[12–14] We started treatment and data collection in the acute phase of pulmonary edema when the patients were not yet instrumented for detailed hemodynamic assessment. Therefore, we cannot distinguish between the possible direct cardiovascular effects of CPAP and the indirect effects of improved pulmonary function, nor can we compare the relative importance of improved oxygenation and decreased respiratory work in relieving circulatory stress.

TABLE IV Causes of Failure of the Assigned Treatment*

	Control (n = 20)	CPAP (n = 20)
Failure criteria met before treatment	12	10
Failure during follow-up	13	7
Pa_{O_2} <50 mm Hg	9	4
Pa_{CO_2} >55 mm Hg	0	1
Respiratory rate >35 breaths/min	2	1
Cardiopulmonary resuscitation	1	1
Artificial airway required	1	0
Mechanically ventilated	12	6
Survived	14	17

* Differences not statistically significant.
CPAP = continuous positive airway pressure.

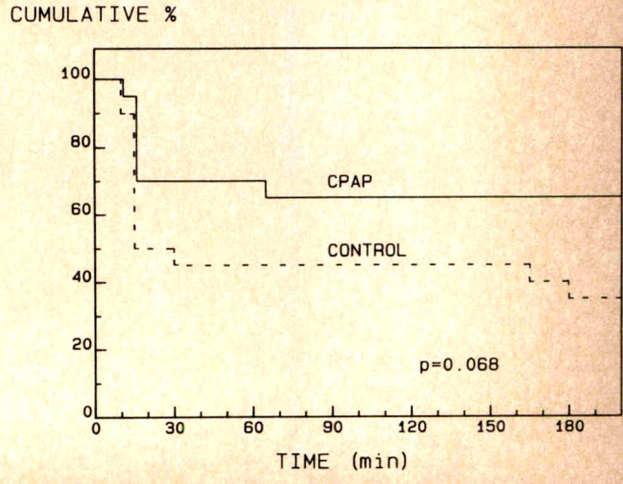

FIGURE 2. Cumulative percentage of patients remaining in the study during the 3-hour observation period. CPAP = continuous positive airway pressure.

The assigned therapy was not sufficient to prevent the need for mechanical ventilation in one-third of the patients who received CPAP, and in two-thirds of those who breathed with an ambient airway pressure ($p = 0.068$). A study involving more patients is required to confirm or refute the clinical significance of this trend and to determine whether early CPAP therapy has an effect on the outcome of patients who present with cardiogenic pulmonary edema. Some of the therapeutic failures may have been avoided in both groups by allowing adjustment of inspired oxygen and CPAP levels. Because the therapeutic effect of increased alveolar oxygen partial pressure depends on the magnitude of intrapulmonary shunt,[15–17] appropriate administration of CPAP can be expected to enhance the effect of supplemental oxygen particularly when the shunt is large. Thus, the elevation of inspired oxygen concentration in this study would have produced similar or even larger differences in gas exchange between the groups.

We conclude that 10 cm H_2O of continuous positive airway pressure administered by face mask improves gas exchange, decreases respiratory work, unloads circulatory stress, and may reduce the need for ventilator treatment in patients with acute cardiogenic pulmonary edema. Because of its safety, simplicity and reversibility, this technique bridges the gap between the oxygen mask and the ventilator.

Acknowledgment: We thank the physicians, the nursing staff and the laboratory personnel of the Emergency Department and the Intensive Care Unit at Helsinki University Central Hospital for their cooperation. We also are grateful to Markku Kupari, MD, for reviewing the manuscript and to Martha Gaber Abrahamsen for editing it for style.

Intracoronary Thrombolytic Therapy in Acute Myocardial Infarction: A Prospective, Randomized, Controlled Trial

ALBERT E. RAIZNER, MD, FRANCISCO A. TORTOLEDO, MD, MARIO S. VERANI, MD, and RICHARD E. VAN REET, MD, *with* JAMES B. YOUNG, MD, FRANK D. RICKMAN, MD, W. RICHARD CASHION, MD, DAVID A. SAMUELS, MD, CRAIG M. PRATT, MD, MOHAMMED ATTAR, MD, HOWARD S. RUBIN, MD, JOHN M. LEWIS, MD, MILTON S. KLEIN, MD, and ROBERT ROBERTS, MD

A prospective, randomized trial was designed to assess the efficacy of intracoronary thrombolytic therapy with streptokinase (STK) in acute myocardial infarction. Sixty-four patients with acute myocardial infarction were randomized within 6 hours of onset of symptoms to 1 of 3 groups. Sixteen patients were treated by conventional means (control group). Nineteen patients underwent coronary arteriography and received corticosteroids and intracoronary and intravenous nitroglycerin (NTG group). Twenty-nine patients received management identical to that of the NTG group, with the addition of intracoronary STK therapy (STK group). Recanalization was demonstrated in 21 of 29 patients (72%) in the STK group. Global and regional ejection fraction (EF) was determined by radionuclide ventriculography before any intervention and 7 to 10 days later. No significant improvement in global EF was achieved in the control and NTG groups. In STK patients as a group, global EF did not increase significantly; however, in patients recanalized with STK, EF improved from 42 ± 17% to 49 ± 16% ($p = 0.023$). All groups showed wide variability of response. Improvement in global EF of more than 5% was noted in 44% of patients recanalized with STK. When subgrouped on the basis of initial global EF of 45% or less or more than 45%, only patients recanalized with STK with an initial EF of 45% or less had an improved global EF (from 30 ± 10% to 42 ± 10%, $p = 0.015$). Regional EF of all involved infarct regions was improved only in the STK group (from 34 ± 19% to 42 ± 23%, $p = 0.027$) and STK-recanalized subgroup (from 33 ± 18% to 45 ± 24%, $p = 0.003$). When only the most involved infarct regions were analyzed, control, NTG and STK groups improved, with patients recanalized with STK showing the greatest degree of improvement. Thus, this trial demonstrates a beneficial effect of thrombolytic therapy in global and, more strikingly, in regional function in patients in whom recanalization with STK is successful, with predominant benefit in those with initially depressed left ventricular function.

(Am J Cardiol 1985;55:301–308)

Nonsurgical revascularization in acute myocardial infarction (AMI) has been achieved with intracoronary administration of streptokinase (STK),[1–10] and initial studies suggested that successful thrombolysis improves ventricular performance. More recently, prospective, randomized controlled studies have been published,[11–13] but conclusions regarding effects on left ventricular function conflict. Because most STK trial protocols include a variety of medications, such as corticosteroids, vasodilators and anticoagulants, which may themselves contribute to beneficial results, we felt that a group should be treated identically to the patients receiving STK except for the omission of STK. Accordingly, we performed such a study using a prospective, randomized trial design.

Methods

Patients admitted to The Methodist Hospital, Houston, with prolonged chest pain were considered for entry to the study if they met the following criteria: (1) chest discomfort suggestive of myocardial ischemia lasting more than 1 hour

From the Section of Cardiology, Baylor College of Medicine, and The Methodist Hospital, Houston, Texas. This study was supported by The Methodist Hospital, Houston, Texas. Manuscript received September 18, 1984; revised manuscript received November 1, 1984, accepted November 2, 1984.

and not relieved by nitroglycerin (NTG); (2) electrocardiographic abnormalities compatible with AMI, consisting of ST-segment elevation or depression greater than 1 mV, or the development of new Q waves; and (3) onset of chest discomfort within 6 hours of arrival at the hospital. Myocardial infarction was confirmed by serial analysis of plasma MB-creatine kinase. Criteria for exclusion were: (1) cardiogenic shock; (2) 70 years of age or older; (3) presence of actively bleeding lesions; (4) severe hypertension (blood pressure greater than 200 mm Hg systolic or 120 mm Hg diastolic); (5) stroke within the preceding 2 weeks; (6) major surgery within the preceding 2 weeks; and (7) treatment with STK within 1 year or known hypersensitivity to STK. Patients meeting the entry criteria were informed of the nature of the study, and if they consented to participate, were randomized to 1 of 3 groups by a computer-generated random sequence.

Patients in group I (control group) received standard care in the coronary care unit as per usual practice. Coronary arteriography was not performed on admission in this group, but was done in most patients within 3 weeks. Anticoagulant drugs were not routinely administered to these patients.

Patients in groups II and III underwent right- and left-sided cardiac catheterization with coronary angiography by either the brachial or femoral artery approach under systemic anticoagulation with 5,000 units of heparin. Multiple projections were obtained of both coronary arteries and the vessel responsible for the infarction was identified. Patients in group II (NTG group) received intracoronary NTG, 0.2 to 0.4 mg, in the infarct-related artery followed by repeat coronary angiograms 3 to 5 minutes later. Patients in group III (STK group) received, in addition to intracoronary NTG as in group II, intracoronary STK given as a bolus of 20,000 IU in 2 to 3 minutes, followed by an infusion at the rate of 4,000 IU/min, which was continued until a dose of 250,000 IU was administered. Repeat arteriograms were obtained every 15 minutes. Both NTG and STK groups received 5 mg of Decadron® intravenously before coronary arteriography. Patients in both groups received intravenous NTG, 50 to 70 μg/min, for 24 hours under hemodynamic monitoring, followed by oral or topical nitrates. They also received dipyridamole, 75 mg orally 3 times/day; aspirin, 5 grains/day orally; and heparin, 5,000 IU subcutaneously every 8 hours until ambulating. Beta-blocking drugs and calcium channel-blocking drugs were avoided unless specifically indicated for arrhythmia or post-infarction angina.

Blood samples were obtained from all 3 groups on admission and every 6 hours for 48 hours for plasma MB-creatine kinase determination by electrophoresis. All 3 groups were given lidocaine, 100 mg i.v. bolus on admission, followed by continuous i.v. infusion of 2 to 4 mg/min for 48 hours.

To allow for the fact that not all STK (group III) patients would be successfully recanalized and to provide a sufficient number of patients in the STK group to analyze "recanalized" and "nonrecanalized" subgroups, 50% of patients were randomized to group III and only 25% each were randomized to groups I and II.

Radionuclide ventriculography: After intravenous injection of 20 mCi of technetium-99m for red cell labeling, radionuclide blood pool ventriculograms were obtained in the left anterior oblique projection with the best septal separation (usually 30 to 40°). The first study was obtained on admission, before cardiac catheterization, and the study was repeated 7 to 10 days later using the same gamma camera.

Global and regional left ventricular ejection fractions (EF) were determined using commercially available software (Technicare). Regional EFs were calculated using a modification of a previously reported technique.[14] The left ventricular silhouette was bisected from base to apex and divided into 3 equal segments of approximately 120° each: septal, inferoapical and posterolateral segments.

All of the radionuclide studies were processed and interpreted by 1 experienced observer without knowledge of the patients' group, clinical or angiographic result or whether the study was being performed before or after treatment. In our laboratory, the inter- and intraobserver correlation coefficients are, respectively: global EF, 0.97 and 0.95; septal EF, 0.82 and 0.86; inferoapical EF 0.97 and 0.97; and posterolateral EF, 0.97 and 0.88. The normal value in our laboratory for global left ventricular EF is 64 ± 6% and for regional EF as follows: septal, 66 ± 13%, inferoapical, 63 ± 7%; and posterolateral, 67 ± 9%.

Regional left ventricular function of the areas involved in the infarction were analyzed in 2 ways: *All involved regions*—anterior infarctions tended to involve more than 1 segment, whereas inferior infarctions typically involved only 1 segment. *Most involved region*—the 1 segment per patient with the lowest regional EF. In patients with anterior infarction, this was either the septal or inferoapical segment. In patients with inferior infarction, this was either the inferoapical or posterolateral segment.

Coronary arteriographic data: We categorized the pretreatment infarct-related arteries as completely obstructed or subtotally obstructed. Complete obstruction was defined as the total absence of anterograde flow across the obstructed

TABLE II Angiographic Findings and Angiographic Response to Intracoronary Intervention

	Control* (n = 11)	Nitroglycerin (n = 19)	Streptokinase (n = 29)

† Significant stenosis considered to be at least 50% luminal diameter narrowing.

segment. Subtotal obstruction was defined as the presence of any anterograde flow across the obstructed segment. In most instances of subtotal obstruction, the flow in the distal vessel was sluggish, delayed in clearing and incompletely filled the distal vessel. In some, however, distal flow and runoff were reasonably good initially; such patients were still treated according to their treatment group.

An infarct-related coronary artery was considered to be "recanalized" if anterograde distal flow and runoff were seen after intervention.

Statistical analysis: Comparison of parameters on admission and 7 to 10 days later was evaluated by means of a paired *t* test. Comparison of frequency distributions between groups was performed with Fisher's exact or chi-square tests. For intergroup comparisons, 1-way analysis of variance was used. Statistical significance was at the $p < 0.05$ level, and results are reported as mean ± standard deviation.

Results

Patient characteristics: Sixty-six patients met initial entry criteria and were randomized to a treatment group. Two patients were subsequently excluded for failure to evidence elevation of MB-creatine kinase. Of the remaining 64 patients, 16 were randomized to the control group, 19 to the NTG group and 29 to the STK group. The clinical characteristics of the 3 groups at entry into the study are shown in Table I. There were no statistically significant differences between groups.

Angiographic findings: The baseline angiographic findings and the results of intracoronary intervention in the NTG and STK groups are shown in Table II.

Overall, complete occlusion of the infarct-related vessel was observed in 60% of all patients in the NTG and STK groups combined. Of the 29 patients who received intracoronary STK, 16 initially had a complete obstruction. In 8 of these patients the completely occluded arteries opened unequivocally to allow anterograde flow after STK infusion. In the 13 patients with subtotal obstruction, it was more difficult to assess improvement in flow because some anterograde flow was present initially. However, 8 of these 13 showed a reduction in the severity of stenosis and an increase in rate of contrast runoff; 5 others manifested equivocal improvement. Thus, 21 patients (72%), consisting of 8 who had initially complete obstruction and 13 with subtotal obstruction, had distal flow in the infarct-related artery after STK infusion and were therefore, considered to be recanalized.

Clinical course: The hospital course and clinical outcome of the 3 groups of patients are shown in Table III. There were no statistically significant differences between groups.

In the entire series, 6 patients died, for an overall mortality rate of 9%. No patients in the control group died, 2 (11%) in the NTG group died and 4 (14%) in the STK group died. In 4 of these 6 patients, the infarct-related artery remained occluded after intervention. Of the 2 patients in the NTG group who died, 1 had an admission EF of 22%, and the other died despite an

initial EF of 49% when severe hypotension developed after intracoronary NTG treatment. In the STK group, 3 of the 4 patients who died had extremely low admission EFs (12%, 19% and 23%). None of these patients had successful recanalization with STK. One patient with an admission EF of 57% died after coronary artery bypass surgery, performed because of continued ischemic episodes. This was the only death among STK-recanalized patients.

Assessment of left ventricular function: Radionuclide ventriculograms done on admission, before any intervention (early study) and at 7 to 10 days after infarction (late study) were available in 16 (100%) of the control patients, 16 (84%) of NTG patients and 22 (76%)

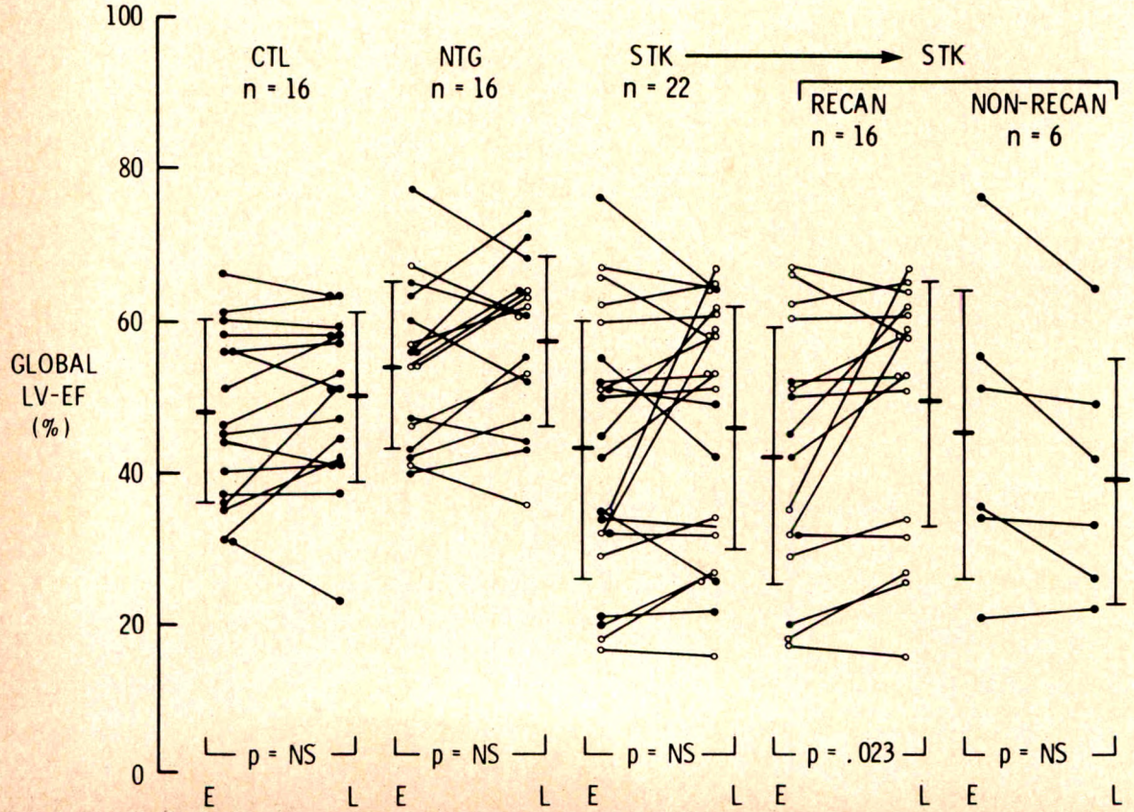

FIGURE 1. Global left ventricular ejection fraction (LV-EF) early (E) (before intervention) and late (L) (7 to 10 days) in the 3 study groups: Control (CTL), nitroglycerin (NTG) and streptokinase (STK). The STK group is separated into recanalized (RECAN) and nonrecanalized (NON-RECAN) subgroups. In the NTG and STK groups, **closed circles** indicate a completely occluded artery and **open circles** incomplete occlusion or recanalization.

of the STK patients. These data are shown in Table IV and individual measurements are shown in Figures 1 to 4.

The initial EF was somewhat lower in the STK group, but differences between the groups were not statistically significant. There were no statistically significant changes in left ventricular global EF from early to late study in either of the 3 groups. Much variability of response was seen within each group; global EF increased impressively in some patients and decreased in others (Fig. 1). When the patients in the STK group were separated into recanalized and nonrecanalized subgroups, global left ventricular EF increased significantly (from 42 ± 17% to 49 ± 16%, p = 0.023) in patients with recanalized vessels. An opposite trend was observed in those patients whose infarct-related vessel remained occluded (from 45 ± 19% to 39 ± 16%), but this latter change narrowly failed to achieve statistical significance (p = 0.06).

When the STK-recanalized group was further subdivided based on an early EF of 45% or less or more than 45%, the global EF significantly improved in patients whose initial EF was 45% or less, but showed no significant change in patients whose initial EF was more than 45% (Fig. 2). The prevalence of anterior infarction was higher in the subgroup with initially depressed EF (8 of 9) while inferior infarction predominated in those with normal EF (6 of 7) (p <0.01). There were no significant differences between early and late global EF in the control and NTG groups when similarly subdivided according to initial EF (Fig. 2).

Subdividing the STK-recanalized patients into those whose infarct-related artery was incompletely occluded (subtotal) before treatment and those with initially complete occlusion revealed a comparable magnitude of improvement in global EF in both subgroups. Global EF in the former subgroup increased from 44 ± 20% to 51 ± 18% (p = 0.1, n = 10) and in the latter subgroup from 40 ± 12% to 46 ± 18% (p = 0.08, n = 6). Similar subdivision of the NTG group showed no greater improvement in global EF among those with incomplete occlusion before treatment (from 53 ± 9% to 57 ± 11%, p = 0.3, n = 6) compared to those with complete occlusion (from 55 ± 12% to 58 ± 11%, p = 0.3, n = 10).

Regional left ventricular ejection fraction: Data on regional left ventricular function of the areas involved in the infarction are shown in Table IV.

All involved segments: There was much variability of response in all groups (Fig. 3). Some patients in each group showed large increases and other decreases in regional EF. A statistically significant improvement in the mean regional EF was observed only in the STK group (from 34 ± 19% to 42 ± 23%, p = 0.027). No statistically significant change in regional function was observed in the control or NTG groups. Additionally, in the STK-recanalized patients EF improved more markedly from 33 ± 18% to 45 ± 24% (p = 0.003). In contrast, nonrecanalized patients tended to have de-

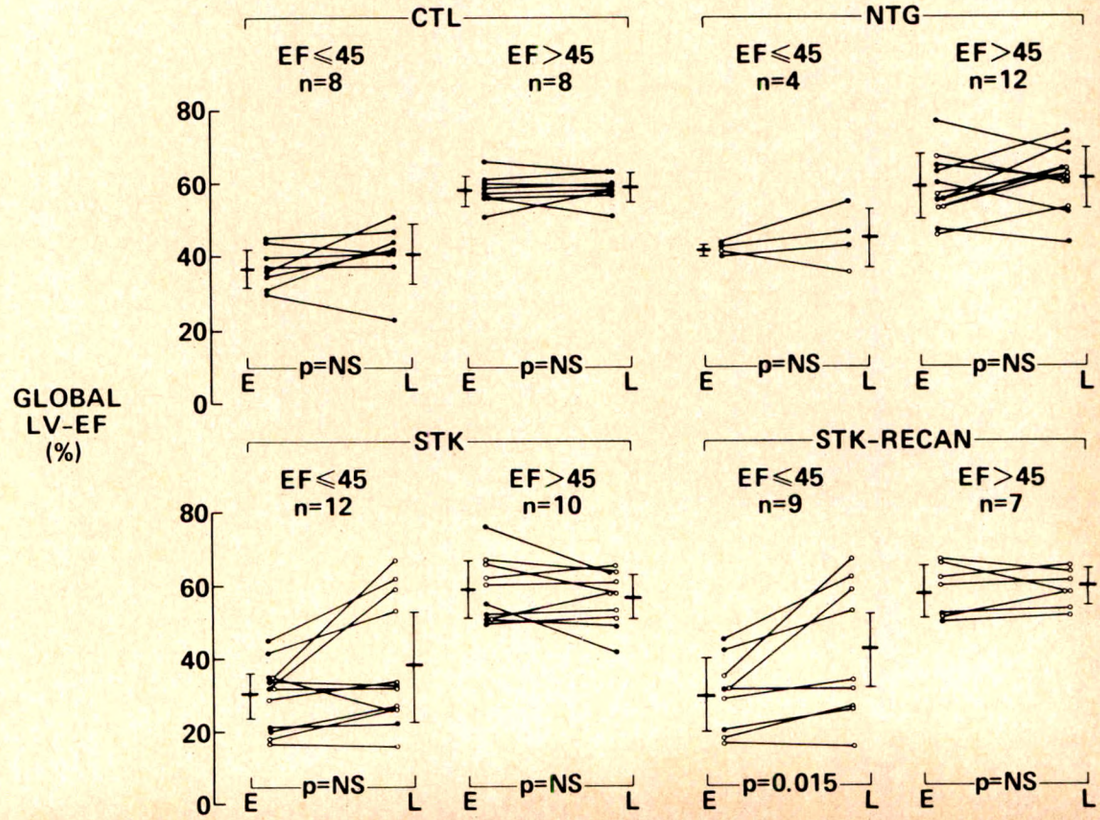

FIGURE 2. Global left ventricular ejection fraction (LV-EF) in the study groups, subdivided according to EF on admission. Abbreviations and symbols as in Figure 1.

terioration in regional EF (from 37 ± 24% to 32 ± 18%), although this change was not statistically significant.

Most involved segments: When only the infarct segments whose EF was most depressed were analyzed, statistically significant improvement in regional EF was observed in the control, NTG, STK and STK-recanalized groups (Fig. 4, Table IV). The greatest magnitude of improvement, however, occurred in the STK-recanalized patients, whose infarct-region EF increased from 30 ± 17% to 48 ± 27% ($p = 0.003$).

Discussion

Our study addresses the hypothesis that nonsurgical coronary artery recanalization in patients with AMI improves left ventricular function. With this aim, we designed a prospective, controlled study in which patients were randomized to 1 of 3 groups. This study design is unique relative to previously reported randomized trials in using 2 control groups, including a group (NTG) managed identically to the treatment group (STK) except for STK therapy. The primary endpoint in this short-term study was left ventricular function as measured by global and regional EF. The results of this study support the hypothesis that recanalization with thrombolytic therapy results in improved left ventricular function following AMI with improved function occurring in the segments involved with infarction. Additionally, the greatest benefit appears to be in those patients with more serious indication of initial myocardial dysfunction. Lack of improvement or deterioration in global EF was noted in those in whom the infarct vessel remained occluded. A similar observation was made by Timmis et al.[7]

The conclusion that thrombolytic therapy improves global left ventricular function needs qualification. The benefits in left ventricular function observed in the STK-recanalized subgroup is not seen in all patients within this subgroup (Fig. 1 and 2). In fact, in only 7 of 16 patients (44%) in this subgroup did global EF improve by 5% or more, and in only 4 of 16 (25%) did it improve by 10% or more. These few patients who benefited form the basis for the subgroup's mean improvement. Improvement in global EF of 5% or more was observed in 5 of 16 control patients (31%) and 7 of 16 NTG patients (44%). These latter groups, as with the STK group, manifested much individual variability, offsetting the gains in global EF in some.

Analysis of regional EF further substantiates the benefits of successful recanalization. When all infarct-involved segments are analyzed, only the STK and STK-recanalized patients manifest statistically significant improvement. Again, variability among patients within each group is prominent. When only the most involved (most depressed) segment for each patient is tabulated, significant improvement in regional EF is observed for the control, NTG and STK groups, and

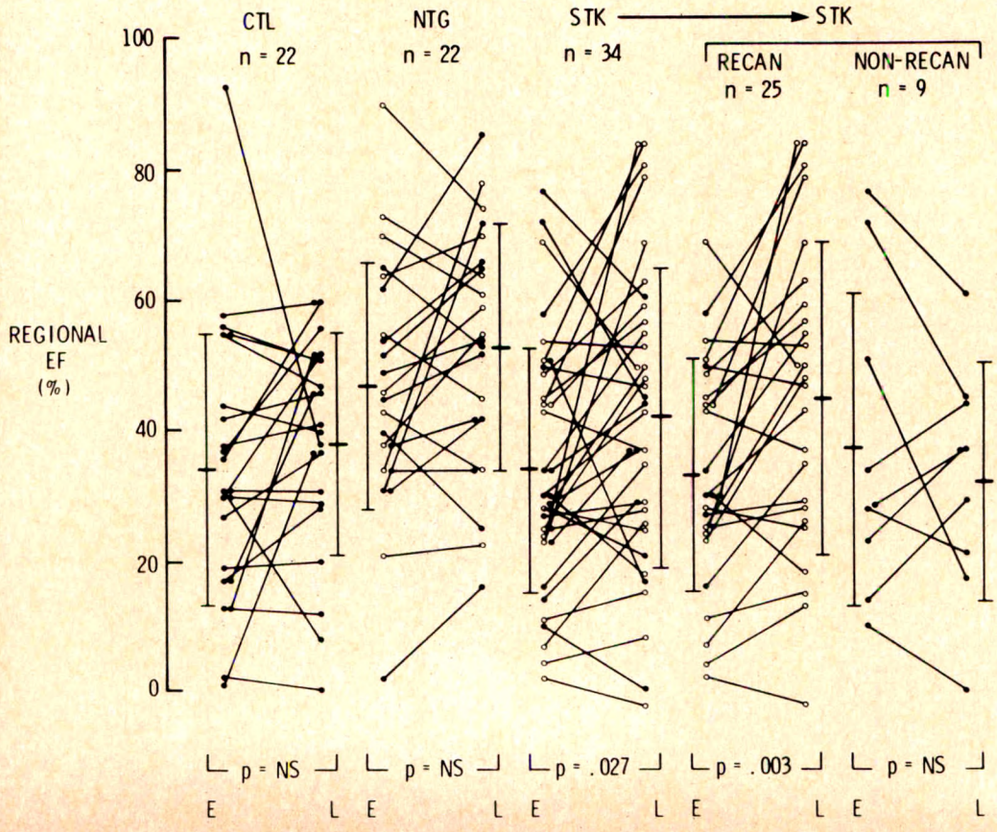

FIGURE 3. Regional ejection fraction (EF) of all involved regions. Early (E) (before intervention) and late (L) (7 to 10 days) in the study groups. Abbreviations and symbols as in Figure 1.

STK-recanalized subgroup. This observation would support the concept of "stunned" but viable myocardial tissue within the infarct region, capable of regaining function with time.[15] The magnitude of regional improvement was greatest in STK-recanalized patients. Improvement in regional function, however, does not directly translate into improved global function. Global EF may not change if noninvolved regions initially hypercontract and gradually return to normal as infarct-involved regions improve.[16] Consequently, regional EF may be a more sensitive measure of a beneficial effect of thrombolytic therapy, and appropriately so, because AMI is primarily a segmental disease. The apparently conflicting results of the randomized studies by Anderson et al,[11] Khaja et al[12] and the Western Washington trial[13] may be explained by the failure to examine early and late regional function in these studies.

Of major importance is the observation that the greatest improvement in left ventricular global and regional function was observed among patients whose EF was substantially reduced (≤45%) on admission. In those patients, EF increased from 30 ± 10% to 42 ± 10% ($p = 0.015$) when recanalization was achieved. These are the patients who would probably benefit with an aggressive intervention. Overwhelmingly, this group was composed of patients with anterior infarction. Thus, we have identified a subgroup of patients, those with initially depressed left ventricular function and, in particular, anterior infarction with depressed left ventricular function, in whom intracoronary thrombolytic therapy appears to be most efficacious. The clinical implication of this latter observation is important. Were intracoronary thrombolytic therapy to be used on a routine basis, the cost in terms of medical manpower, hospital manpower, facility utilization and public cost would be enormous. Applying this procedure to those who appear to benefit most may be a reasonable goal.

Intravenous Versus Intracoronary Streptokinase in Acute Myocardial Infarction

RUSSELL P. VALENTINE, MD, DOUGLAS E. PITTS, MD,
JO ANN BROOKS-BRUNN, RN, MSN, JAMES G. WILLIAMS, MS,
EUGENE VAN HOVE, MD, and PAUL E. SCHMIDT, MD

One hundred sixty-four consecutive patients with acute myocardial infarction were enrolled in a prospective trial of coronary thrombolysis with streptokinase (STK). The first 98 patients received intracoronary (i.c.) STK after coronary angiography and the next 66 received a high-dose rapid infusion of STK (900,000 IU) intravenously (i.v.) before angiography. First-pass radionuclide ejection fraction (EF) was performed early (within 24 hours of admission) and late (10 to 14 days after admission) to evaluate left ventricular function. In the i.v. group, 42 of 66 (64%) of infarct-related arteries were patent at the initial angiogram and 6 (9%) opened with subsequent i.c. STK. In the i.c. group, 13 of 98 (13%) of infarct-related arteries were patent at the initial angiogram and 50 of 85 (59%) opened with the i.c. STK. The i.v. and i.c. groups did not differ in time from onset of chest pain to presentation, type of infarct or underlying severity of coronary artery disease. In the i.v. group, STK was begun 67 minutes earlier than in the i.c. group. In 62 patients in whom reperfusion was successful, mean EF increased from 39 ± 11% early to 48 ± 13% late. In 30 in whom it was not, the mean EF increased from 36 ± 10% to 40 ± 12%. The increase in EF was significantly greater in patients in the reperfused group ($p < 0.03$). In 18 patients who underwent reperfusion by i.v. STK, the mean EF increased 11 ± 12%, whereas in 44 patients who had reperfusion by i.c. STK, the mean EF increased 9 ± 10% (difference not significant). Complications of the lysis procedure were similar in the i.v. and i.c. groups. Thus, i.v. and i.c. STK are of comparable efficacy and safety in establishing reperfusion of the infarct-related artery in patients with acute myocardial infarction.

(Am J Cardiol 1985;55:309–312)

Thrombosis of a coronary artery usually underlies acute myocardial infarction (AMI),[1] and the thrombus can be lysed with regional administration of streptokinase (STK) in most patients.[2–4] There is also evidence that reperfusion improves left ventricular function[5–7] and reduces the mortality rate from AMI.[8] Nevertheless, the intracoronary (i.c.) administration of STK is impractical because of limited access to the facilities and personnel necessary for its use. Intravenous (i.v.) STK does not require specialized facilities and can be performed earlier in the course of AMI. If the efficacy and safety of i.v. STK are comparable to i.c. STK, then its wider applicability and potential for earlier administration could have substantial impact on the treatment of patients with AMI.

We studied 164 consecutive patients in a nonrandomized prospective trial of coronary thrombolysis in patients with AMI. The first 98 patients were treated with i.c. STK (i.c. patients), and the subsequent 66 patients with i.v. STK (i.v. patients). In this report we compare the efficacy and safety of these 2 treatment methods.

Methods

Patients: We prospectively evaluated 191 patients with AMI who presented to the hospital within 6 hours of the onset of chest pain from October 1981 to March 1984. AMI was diagnosed by unequivocal ST-segment elevation, which did

i.v.	66	64	74

i.c. = intracoronary; i.v. = intravenous.

not revert with the administration of nitrates. Patients were excluded for: (1) age over 80 years, (2) active gastrointestinal bleeding within 6 months, (3) cerebrovascular accident within 2 years, (4) surgery within 2 weeks, (5) recent external cardiac massage, and (6) absence of valid consent form. One hundred sixty-four patients who gave informed consent (approved by the Institutional Review Board) were included in this analysis. One hundred thirty-one were men. The average age of the patients was 57.1 ± 9.2 years (range 36 to 78).

Study protocol: *Intracoronary group:* Patients received i.v. heparin, 5,000 U, and an i.v. bolus of lidocaine hydrochloride, 1.0 to 1.5 mg/kg body weight, followed by a continuous infusion of 2 to 4 mg/min. Coronary angiograms were performed using the Seldinger technique and Judkins catheters through a percutaneous sheath. If occlusion of the infarct-related artery persisted after 400 μg of i.c. nitroglycerin, 20,000 IU of STK (Kabikinase®) was administered as a bolus followed by an infusion at 4,000 U/min. Angiography of the vessel was repeated every 15 minutes. The infusion was continued 30 minutes after lysis or until 2 consecutive angiograms showed no change in the amount of i.c. clot. If patency did not occur, the infusion was discontinued after 60 minutes. Left ventriculography was performed after the STK infusion. The average total dose of STK for i.c. patients was 213,000 ± 82,000 IU.

Intravenous group: The patients received 250 mg of i.v. hydrocortisone, an infusion of i.v. lidocaine (see i.c. group) and then 900,000 IU of STK. Cardiac catheterization was then performed, and i.c. STK administered (per i.c. group protocol) if the infarct-related artery was occluded at the time of initial angiography or if significant flow-restricting coronary thrombosis remained. The average total dose of STK for i.v. patients was 993,000 ± 182,000 IU.

After successful lysis, partial thromboplastin time was measured serially, and continuous i.v. heparin was administered to maintain partial thromboplastin time at 2 to 2½ times the control for at least the first 72 hours after the procedure. Aspirin (5 grains twice daily) and dipyridamole (25 mg 3 times daily) were administered orally. The percutaneous sheath was removed 24 to 72 hours after the procedure while the heparin infusion was interrupted briefly. All study patients had documentation of their clinical course, including the incidence of complications. Each patient underwent clinical reevaluation at 2, 6 and 12-month follow-up intervals. First-pass radionuclide ventriculography was performed within 24 hours of admission, at discharge and at the follow-up intervals using technetium-99m-DTPA and a multicrystal camera. Patients who underwent coronary artery bypass grafting before their follow-up nuclear studies were excluded from analysis of ventricular function. Also, patients without total occlusion of the infarct-related artery were not included in this analysis.

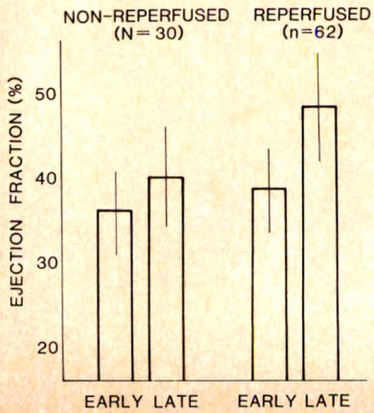

FIGURE 1. Effect of lysis on left ventricular function. Ejection fraction changes from admission (early = within the first 24 hours) to time of discharge (late = 10 to 14 days after admission) in reperfused and nonreperfused patients.

Data analysis: The patency rate of the infarct-related vessel on the initial angiogram and the time from onset of pain to initial administration of the STK were compared in the i.v. and i.c. groups. Comparison of left ventricular ejection fraction (EF) was made between patients who did and did not have successful lysis. Chi-square analysis was used to make these comparisons.

Results

Frequency of reperfusion (Table I): The i.v. and i.c. groups did not differ with respect to time from onset of chest pain to presentation, onset of chest pain to beginning of cardiac catheterization, demographic data or overall severity of coronary artery disease. Of 98 patients in the i.c. group, 13 (13%) had a patent infarct-related artery on initial angiography. Reperfusion occurred in 50 of the 85 (59%) who received i.c. STK. A total of 63 of 99 (64%) had a patent infarct-related artery at the conclusion of the procedure.

Of 66 patients in the i.v. group, 42 (64%) had a patent infarct-related artery on initial angiogram. Reperfusion occurred in an additional 6 patients after receiving i.c. STK for a total patency rate of 48 of 66 (74%). If the 13% incidence of spontaneous patency seen in the i.c. group applies to the i.v. group, then i.v. STK achieved lysis in 51% of patients.

Time to treatment: The mean time from the onset of chest pain to the administration of STK in the i.c. group was 241 ± 72 minutes, and in the i.v. group 174 ± 97 minutes. Therefore, lytic therapy was begun 67 minutes sooner using the i.v. route.

Effect on left ventricular function (Fig. 1): Early (24 hours) and late (10 to 14 days) radionuclide EF data are available in 30 patients in whom reperfusion was not achieved and in 62 in whom it was achieved. In nonreperfused patients, the mean early EF was 36 ± 10%, the mean late EF was 40 ± 12% and the mean increase was 3.8 ± 9.8%. In reperfused patients, the mean early EF was 39 ± 11%, the mean late EF was 48 ± 13% and the mean increase was 9.5 ± 10%. The increase in EF was significantly greater in the reperfused than in the nonreperfused group ($p < 0.03$). The groups did not differ in age, gender, risk factor prevalence or severity of coronary disease. Of the 62 reperfused patients in whom EF data are available, 44 were reperfused by the i.c. route and 18 by the i.v. route. The mean EF increase in i.c. patients was 8.7 ± 9.7% and in i.v. patients 11 ± 12%. These values do not differ significantly.

Complications (Table II): Sustained ventricular tachycardia, nonsustained ventricular tachycardia, or ventricular fibrillation occurred in 23 of 98 i.c. patients

(23%) and 17 of 66 i.v. patients (26%). Bleeding of sufficient magnitude to necessitate transfusion occurred in 5 of 98 i.c. patients (5%) and 2 of 66 i.v. patients (3%). Bleeding was invariably related to the catheterization site and occurred at least 24 hours after the catheterization procedure while patients were receiving heparin, aspirin and dipyridamole. One i.c. patient required direct surgical repair of the femoral artery. Apparent hypersensitivity reaction to STK (hives or other transient erythematous skin eruptions) occurred in 2 i.c. patients (2%) and 2 i.v. patients (3%). In 1 i.c. patient, transient renal failure accompanied a skin rash and an allergic interstitial nephritis was postulated. Hypotension temporally related to STK infusion occurred in 9 i.c. patients (9%) and 11 i.v. patients (17%). Mortality for the entire group was 9.6% and did not differ between lysed and nonlysed or between i.v. and i.c. groups.

TABLE II Complications

Complication	Group	
	i.c. (%)	i.v. (%)
Arrhythmia	23	26
Bleeding requiring transfusion	5	3
Arterial repair	1	0
Rash	2	3
Hypotension	9	17

Abbreviations as in Table I.

Discussion

Intravenous vs intracoronary streptokinase: Our results show that i.v. and i.c. STK are of comparable efficacy in patients with AMI. The incidence of patency of the infarct artery in patients who received i.v. STK was identical to that seen in those given i.c. STK (64%). In 98 patients given i.c. STK studied with coronary angiography, the frequency of spontaneous patency of the infarct-related artery was 13%. This incidence of spontaneous patency is in keeping with the study of DeWood et al[1] who found 10 to 13% of infarct arteries patent within the first 6 hours of infarction. When the i.c. group is used as a historical control group for the i.v. patients and a 13% spontaneous patency rate is assumed, the reperfusion rate attributable to the i.v. STK infusion is 51%, a value not significantly different from the 59% reperfusion rate achieved with i.c. STK. The lysis rates in the 2 groups may be similar because the lysis rate in the i.c. group is lower than in other studies. No apparent reason exists for this seemingly lower efficacy in our i.c. group, because patient selection criteria and treatment methods are similar to those of other studies. The 59% lysis rate seen in our study is not significantly different from the 60% lysis rate in the study of Khaja et al.[9]

The subsequent infusion of i.c. STK in patients who have received i.v. STK, but in whom the infarct artery is still occluded at the time of the initial angiogram, resulted in reperfusion in an additional 6 patients (9%) and a total patency rate of 74%. Whether this additional reperfusion is attributable to the i.c. infusion or to a delayed effect of the i.v. STK is difficult to determine. The latter is a possibility because high-dose systemic STK infusions may deplete all available plasminogen.[10] If this is the case, then i.c. STK infusion after a high-dose systemic STK infusion would be unlikely to have an additional effect. Therefore, the reperfusion rate of 51% with i.v. STK may represent a "minimum" efficacy. The actual rate of reperfusion may be higher if reperfusion achieved after the time of the initial angiogram was really a delayed effect of the i.v. infusion.

The i.v. group did have a significantly shorter interval of pain onset to institution of STK (175 ± 97 minutes) than the i.c. group (241 ± 72 minutes). The interval of pain onset to cardiac catheterization was the same in the 2 groups. Our protocol prevented us from determining the actual time of lysis in the i.v. group. It is tempting to use various clinical changes such as resolution of chest pain, return of ST segments to baseline and reperfusion ectopy to determine time of lysis. Various combinations of these findings were observed in our patients but were not consistently or predictably related to finding a patent artery at cardiac catheterization. No attempt was made to derive a time of lysis for the i.v. group. Nevertheless, because lysis occurred before catheterization in most patients in the i.v. group, lysis probably occurred sooner in i.v. than in i.c. patients.

The safety of i.v. STK was equivalent to that of i.c. STK. The incidence of bleeding complications was the same for each group, even though the i.v. group received a much higher total dosage of STK than the i.c. group. In both groups, bleeding complications occurred beyond 24 hours after conclusion of the catheterization procedure, presumably after STK effects had subsided and while patients were receiving heparin, aspirin and dipyridamole. There appears to be no hazard to percutaneous femoral artery puncture performed after high-dose systemic STK infusion. Hypersensitivity reactions were seen with equal frequency in each group. Transient hypotension temporally related to the STK infusion occurred in 9% of i.c. patients and in 17% of i.v. patients. This difference may be because i.v. patients received their infusions in much closer proximity to receiving nitrates (see Methods), but a dose or rate of administration response to STK cannot be discounted.

Changes in left ventricular function: Patients who underwent reperfusion of their infarct-related artery had an increase in radionuclide EF from admission to time of discharge of 9.5% (from 38.5 to 48.0%). This represents a 25% increase in EF from the admission value. Patients in whom reperfusion was not achieved had an increase in EF of 3.8% (from 36.1 to 39.9%), or an 11% increase from the admission value. The increase in EF seen in reperfused patients is significantly greater than that seen in nonreperfused patients ($p < 0.03$). These results differ from those of 2 earlier studies[9,11] in which radionuclide EF failed to improve after reperfusion. However, in these studies the initial EF was normal and an increase might not be expected to occur. There is agreement with the study of Smalling et al,[6] which showed a similar extent of improvement in EF in reperfused patients. Improvement in EF is seen in both i.v. and i.c. lysis groups (11% with i.v. and 8.7% with i.c., difference not significant).

Study limitations: It is beyond the scope of this study to discuss the issue of randomization of treatment

methods for which previous studies already yielded encouraging results. We elected not to randomize treatment in our trial and must acknowledge that the applicability of our findings is thereby limited. In this study, the test groups were studied sequentially and not concurrently, reflecting the sequential appearance of successful pilot studies, first of i.c. and then of i.v. STK. Therefore, no true control groups exist. Nevertheless, we believe that because selection criteria were identical and demographic data similar for the 2 test groups, valid comparisons of the treatment methods can be made.

As with most studies, the adequacy of the sample size is of concern. Although it can be determined that the lysis rates in the i.v. and i.c. groups do not differ, a type 2 error cannot be excluded; to do so would require a study of over 1,600 patients. This statistical confirmation therefore awaits much larger, multicenter trials.

Acknowledgment: We thank Drs. Kirk Parr and Marlon Jordan for their invaluable assistance in data collection. We also thank the Methodist Hospital Emergency Department for cooperation with patient recruitment and management, and Wanda Giles and Linda Cheatham for typing the manuscript.

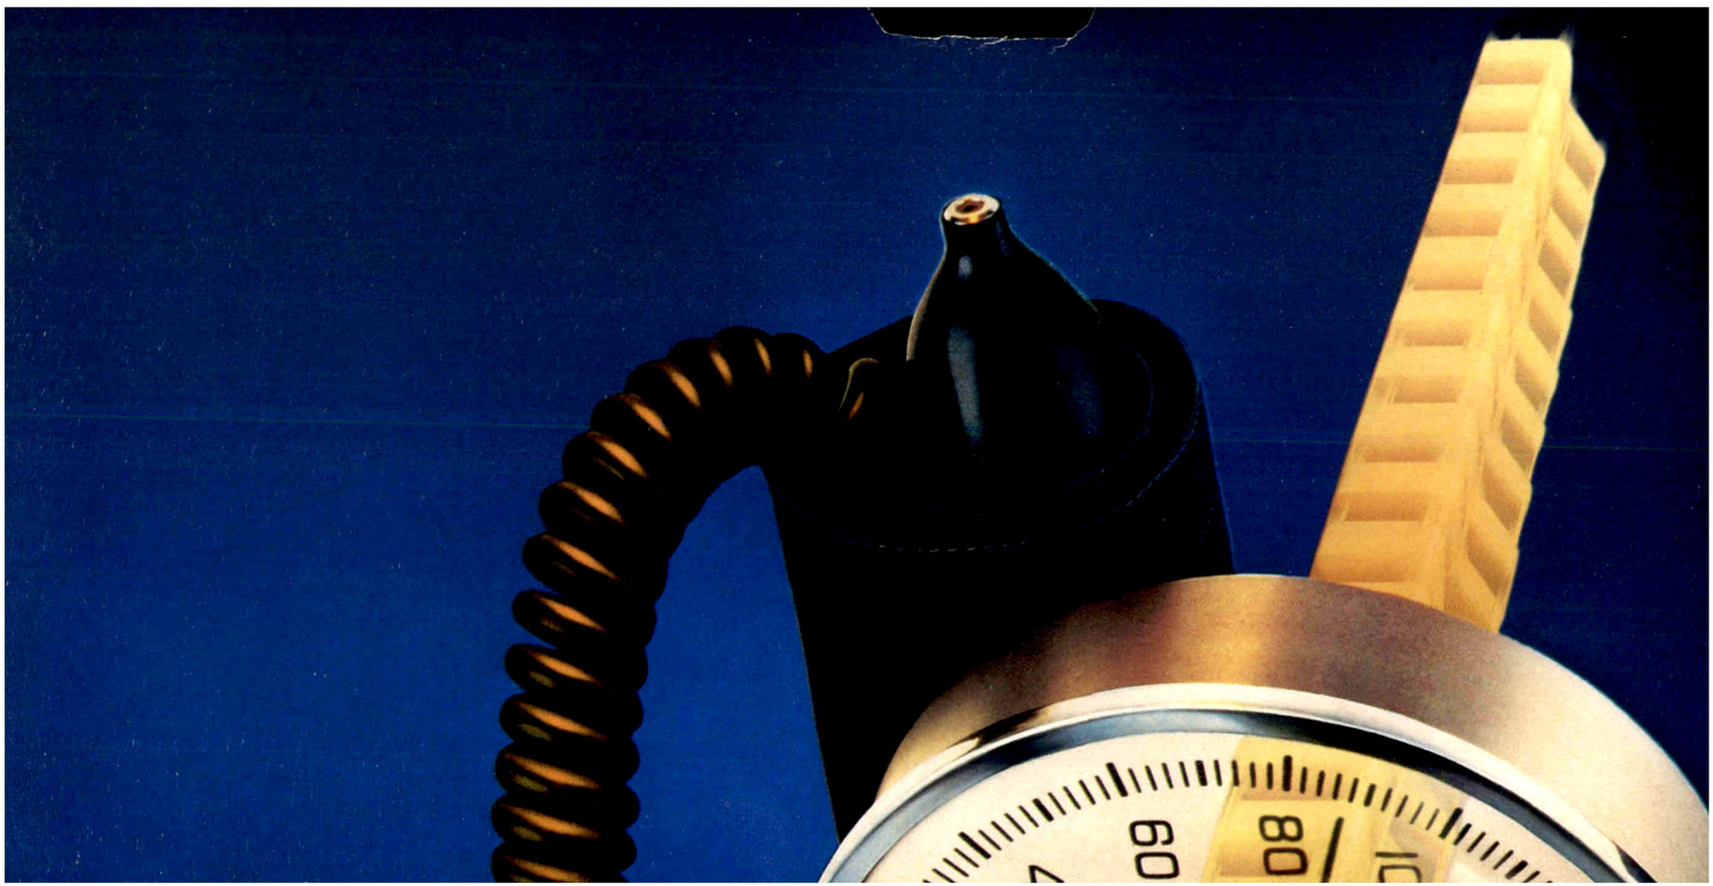
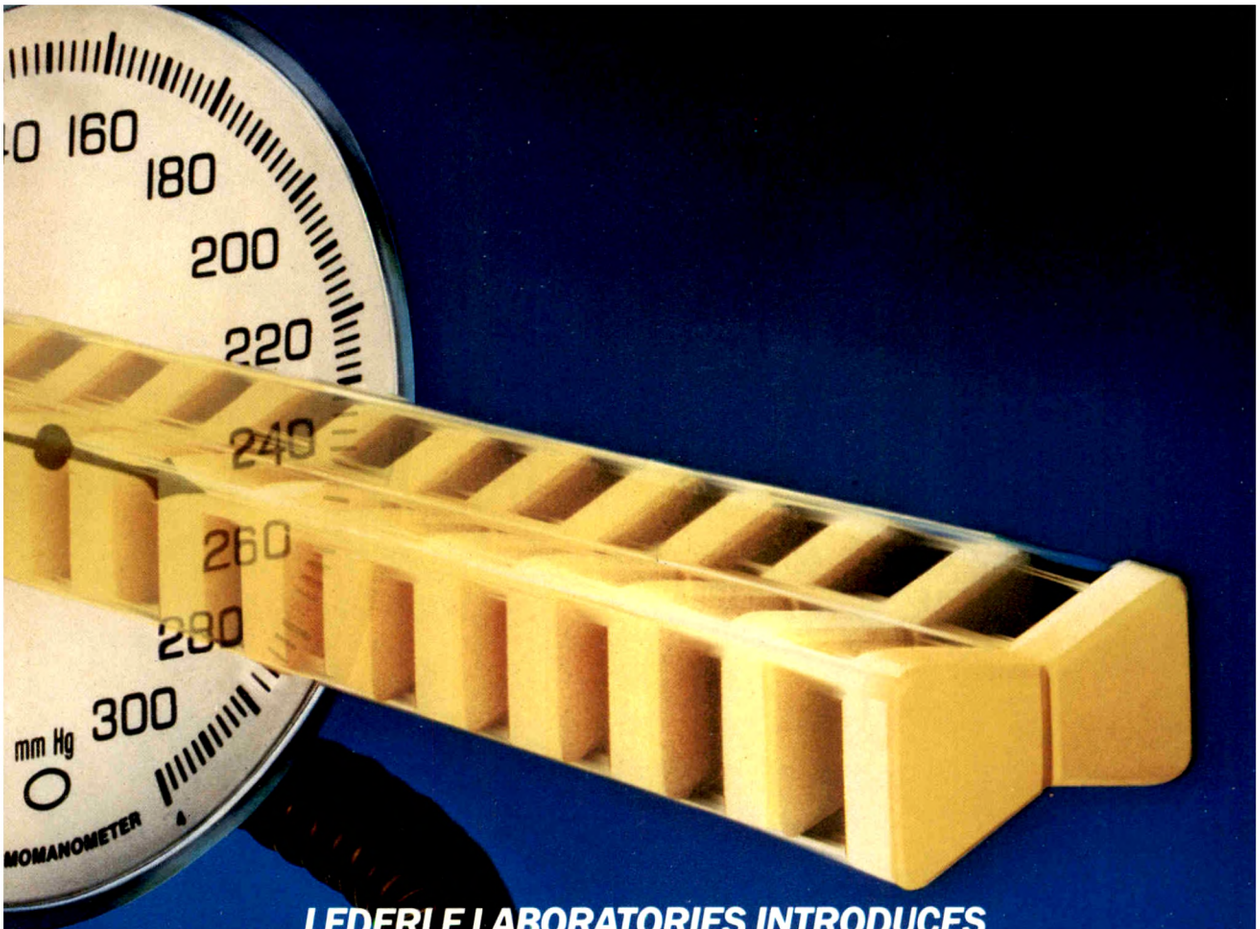
NOW RELEASED...
THE FULL POTASSIUM-SPARING
ANTIHYPERTENSIVE POTENTIAL
OF TRIAMTERENE/





LEDERLE LABORATORIES INTRODUCES

NEW *1 tab q.d.* MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

THE FIRST AND ONLY REPLACEMENT FOR THE LESS BIOAVAILABLE TRIAMTERENE/HYDROCHLOROTHIAZIDE FORMULATION... PROVEN SUPERIOR IN BIOAVAILABILITY

Please see last page of this advertisement for brief summary of prescribing information.

NEW 1 tab q.d.

MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

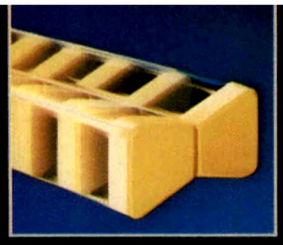
DELIVERS THE PRESCRIBED DOSE...

PROVIDES OPTIMAL ABSORPTION OF 75 MG TRIAMTERENE/ 50 MG HYDROCHLOROTHIAZIDE

A CLINICALLY SAFE AND EFFECTIVE ALTERNATIVE IN POTASSIUM-SPARING, ANTIHYPERTENSIVE THERAPY

- **FOR PATIENTS ON HYDROCHLOROTHIAZIDE WHO DEVELOP HYPOKALEMIA**
- **FOR NEWLY DIAGNOSED PATIENTS IN WHOM THE DEVELOPMENT OF HYPOKALEMIA CANNOT BE RISKED**
- **FOR PATIENTS TRANSFERRED FROM DYAZIDE®***

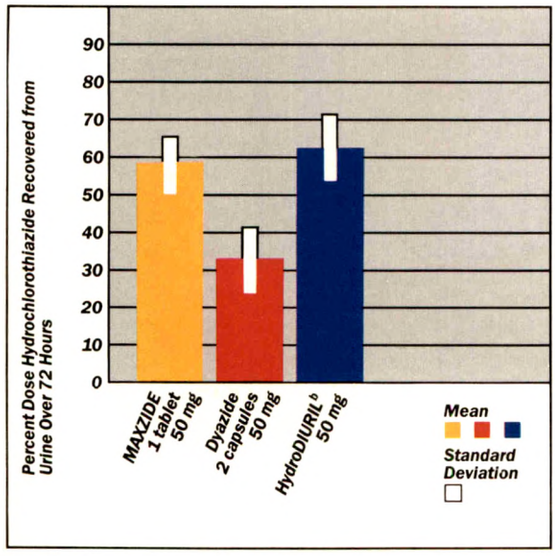
For the first time, a reliable alternative to the Dyazide formulation of triamterene hydrochlorothiazide — new MAXZIDE. In a transfer safety study, patients taking up to four Dyazide capsules daily were effectively transferred to MAXZIDE q.d. with no compromise in clinical condition.[1]



SUPERIOR DRUG DELIVERY AND ABSORPTION — TABLET TO TABLET, PATIENT TO PATIENT

MAXZIDE is optimally bioavailable and consistently delivers the prescribed dose of 75 mg triamterene and 50 mg hydrochlorothiazide. Dyazide, on the other hand, exhibits poor bioavailability. When given in equivalent doses, Dyazide delivers approximately half the amount of hydrochlorothiazide as MAXZIDE. Similarly, two Dyazide capsules deliver less than half the amount of triamterene as one MAXZIDE tablet.[2]

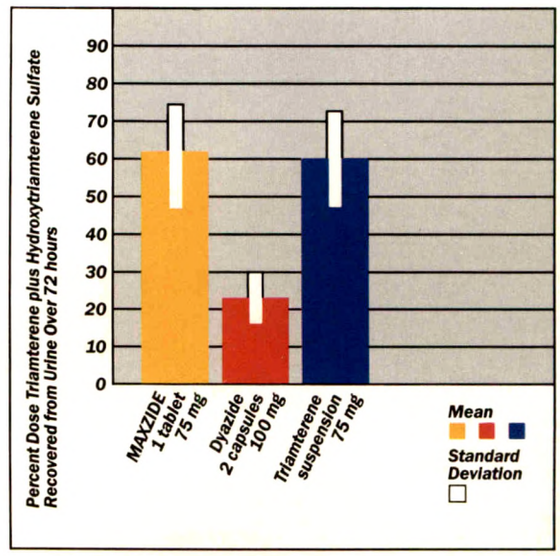
Percent dose of hydrochlorothiazide recovered from urine over 72 hours in subjects[a] given single oral doses



[a]Data from a study of 24 subjects.

[b]HydroDIURIL is the registered trademark of Merck & Co., Inc., for hydrochlorothiazide.

Percent dose of triamterene recovered from urine over 72 hours in subjects[a] given single oral doses



[a]Data from two studies of 24 subjects each.

MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

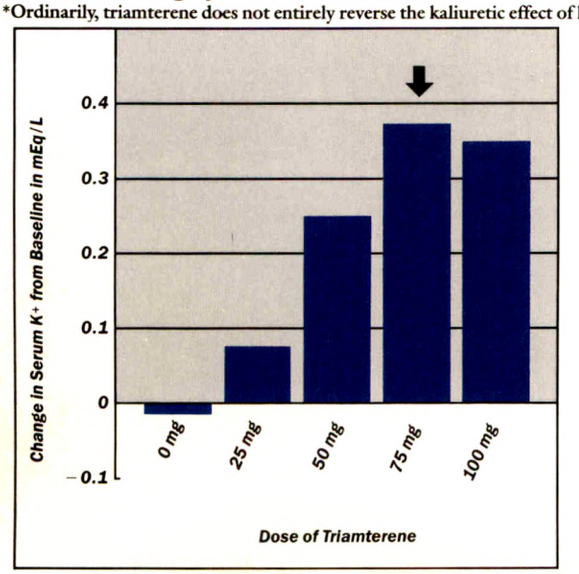
HYDROCHLOROTHIAZIDE EFFECTIVENESS WITH THE OPTIMAL DOSE OF TRIAMTERENE FOR POTASSIUM CONSERVATION

PROVEN FORMULATION MAXIMIZES POTASSIUM-SPARING EFFECT OF TRIAMTERENE

In a clinical dose-response evaluation, 75 mg triamterene daily most successfully corrected the hypokalemic effect of repeated daily doses of 50 mg hydrochlorothiazide.[3*]

Dose-response evaluation of triamterene's potassium-sparing activity in patients[a] rendered hypokalemic with long-term daily doses of 50 mg hydrochlorothiazide

*Ordinarily, triamterene does not entirely reverse the kaliuretic effect of hydrochlorothiazide.



[a]Data from a study of 49 patients.

CLINICALLY SAFE AND WELL TOLERATED

MAXZIDE can be prescribed with confidence for patients transferred from Dyazide to provide the administered dose of hydrochlorothiazide while maintaining clinically acceptable serum potassium levels. Patients previously receiving no diuretic medication and patients previously taking up to four Dyazide capsules daily have been successfully treated with MAXZIDE q.d. with no compromise in clinical condition.[1†]

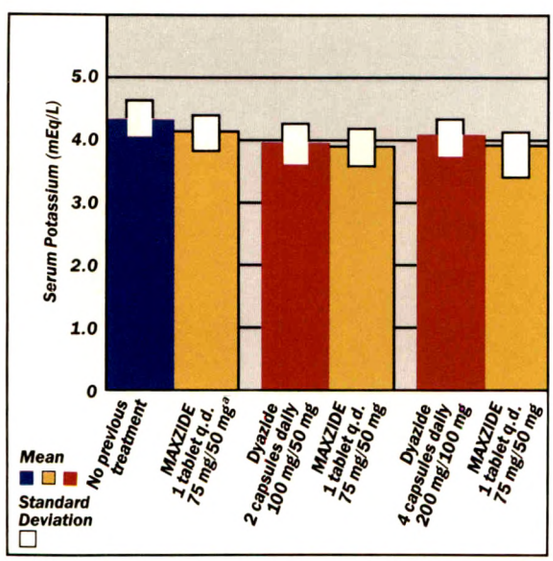
No clinically significant changes in serum potassium levels after 4 weeks of therapy with MAXZIDE one tablet q.d. in 138 patients previously untreated or transferred from Dyazide



[a]All dose ratios listed as triamterene in mg/hydrochlorothiazide in mg.

[†]Abnormal elevation of serum potassium levels (≥ 5.5 mEq/liter) can occur with all potassium-conserving diuretic combinations, including MAXZIDE. Hyperkalemia is more likely to occur in patients with renal impairment, diabetes (even without evidence of renal impairment), or in elderly or severely ill patients. Since uncorrected hyperkalemia may be fatal, serum potassium levels must be monitored at frequent intervals especially in patients first receiving MAXZIDE, when dosages are changed or with any illness that may influence renal function.

NEW *1 tab q.d.*

MAXZIDE™

Triamterene **75 mg**/Hydrochlorothiazide **50 mg**/Lederle

— FOR PATIENTS ON HYDROCHLOROTHIAZIDE WHO DEVELOP HYPOKALEMIA
— FOR NEWLY DIAGNOSED PATIENTS IN WHOM THE DEVELOPMENT OF HYPOKALEMIA CANNOT BE RISKED
— FOR PATIENTS TRANSFERRED FROM DYAZIDE

BRIEF SUMMARY

Please see package insert for full prescribing information.

INDICATIONS AND USAGE: *MAXZIDE is indicated for the treatment of hypertension or edema in patients who develop hypokalemia on hydrochlorothiazide alone. It is also indicated for those patients who require a thiazide diuretic and in whom the development of hypokalemia cannot be risked (e.g., patients on digitalis preparations or with a history of cardiac arrhythmias, etc.).* ***This fixed combination drug is not indicated for the initial therapy of edema or hypertension except in individuals in whom the development of hypokalemia cannot be risked.*** *MAXZIDE may be used alone or in combination with other antihypertensive drugs such as beta-blockers. Since MAXZIDE may enhance the actions of these drugs, dosage adjustments may be necessary. Usage in Pregnancy: The routine use of diuretics in an otherwise healthy woman is inappropriate and exposes mother and fetus to unnecessary hazards. Diuretics do not prevent development of toxemia in pregnancy, and there is no satisfactory evidence that they are useful in the treatment of developed toxemia.*

CONTRAINDICATIONS: *Hyperkalemia: MAXZIDE should not be used in the presence of elevated serum potassium levels (greater than 5.5 mEq/liter). If hyperkalemia develops, this drug should be discontinued and a thiazide alone should be substituted. Concomitant use with other potassium conserving agents such as spironolactone, amiloride HCl or other formulations containing triamterene. Concomitant potassium supplementation in the form of medication, potassium-containing salt substitute or potassium-enriched diets should also not be used. Contraindicated in patients with anuria, acute and chronic renal insufficiency or significant renal impairment. Hypersensitivity to either component separately or other sulfonamide-derived drugs.*

WARNINGS: *Hyperkalemia.*

> *Abnormal elevation of serum potassium levels (greater than or equal to 5.5 mEq/liter) can occur with all potassium conserving agents including MAXZIDE. Hyperkalemia is more likely to occur in patients with renal impairment, diabetes (even without evidence of renal impairment), or elderly or severely ill patients. Since uncorrected hyperkalemia may be fatal, serum potassium levels must be monitored at frequent intervals especially in patients first receiving MAXZIDE, when dosages are changed, or with any illness that may influence renal function.*

If hyperkalemia is suspected, (warning signs include paresthesias, muscular weakness, fatigue, flaccid paralysis of the extremities, bradycardia and shock) an electrocardiogram (ECG) should be obtained. Monitor serum potassium levels because mild hyperkalemia may not be associated with ECG changes. If hyperkalemia is present, MAXZIDE should be discontinued immediately and a thiazide alone should be substituted. If the serum potassium level exceeds 6.5 mEq/liter, more vigorous therapy is required. The clinical situation dictates the procedures to be employed. These include the intravenous administration of calcium chloride solution, sodium bicarbonate solution and/or the oral or parenteral administration of glucose with a rapid acting insulin preparation. Cationic exchange resins such as sodium polystyrene sulfonate may be orally or rectally administered. Persistent hyperkalemia may require dialysis. The development of hyperkalemia associated with potassium-sparing diuretics is accentuated in the presence of renal impairment (see CONTRAINDICATIONS). Patients with mild renal functional impairment should not receive this drug without frequent and continued monitoring of serum electrolytes. Cumulative drug effects may be observed in patients with impaired renal function. The renal clearances of hydrochlorothiazide, the pharmacologically active metabolite of triamterene, and the sulfate ester of hydroxytriamterene have been shown to be reduced and the plasma levels increased following MAXZIDE administration to elderly patients and patients with impaired renal function. Hyperkalemia has been reported in diabetic patients with the use of potassium conserving agents even in the absence of apparent renal impairment. Avoid MAXZIDE in diabetic patients. If it is employed, serum electrolytes must be frequently monitored. Metabolic or Respiratory Acidosis: Potassium conserving therapy should also be avoided in severely ill patients in whom respiratory or metabolic acidosis may occur, since acidosis may be associated with rapid elevations in serum potassium levels. If MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg is employed, frequent evaluations of acid/base balance and serum electrolytes are necessary.

PRECAUTIONS: *Electrolyte Imbalance and BUN Increases: Patients receiving MAXZIDE should be carefully monitored for fluid or electrolyte imbalances, i.e., hyponatremia, hypochloremic alkalosis, hypokalemia and hypomagnesemia. Serum and urine electrolyte determinations should be frequently performed and are especially important when the patient is vomiting or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance include: dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia and gastrointestinal disturbances such as nausea and vomiting.*

Any chloride deficit during thiazide therapy is generally mild and usually does not require any specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt, except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hypokalemia may develop with thiazide therapy, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids, ACTH, amphotericin B or after prolonged thiazide therapy. However, hypokalemia of this type is usually prevented by the triamterene component of MAXZIDE.

Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Hypokalemia can sensitize or exaggerate the response of the heart to the toxic effects of digitalis (e.g., increased ventricular irritability).

MAXZIDE may produce an elevated blood urea nitrogen level (BUN), creatinine level or both. This is probably not the result of renal toxicity but is secondary to a reversible reduction of the glomerular filtration rate or a depletion of the intravascular fluid volume. Periodic BUN and creatinine determinations should be made especially in elderly patients, patients with suspected or confirmed hepatic disease or renal insufficiencies. If azotemia increases, MAXZIDE should be discontinued.

Hepatic Coma: MAXZIDE should be used with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. Renal Stones: Triamterene has been reported in renal stones in association with other calculus components. MAXZIDE should be used with caution in patients with histories of renal lithiasis. Folic Acid Deficiency: Triamterene is a weak folic acid antagonist and may contribute to the appearance of megaloblastosis in instances where folic acid stores are decreased. In such patients, periodic blood evaluations are recommended. Hyperuricemia: Hyperuricemia may occur or acute gout may be precipitated in certain patients receiving thiazide therapy. Metabolic and Endocrine Effects: The thiazides may decrease serum PBI levels without signs of thyroid disturbance.

Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid gland with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged thiazide therapy. The common complications of hyperparathyroidism such as renal lithiasis, bone resorption, and peptic ulceration have not been seen. Thiazides should be discontinued before carrying out tests for parathyroid function.

Insulin requirements in diabetic patients may be increased, decreased or unchanged. Latent diabetes mellitus may become manifest during thiazide administration. Hypersensitivity: Sensitivity reactions to thiazides may occur in patients with or without a history of allergy or bronchial asthma.

Possible exacerbation or activation of systemic lupus erythematosus by thiazides has been reported. Drug Interactions: Thiazides may add to or potentiate the action of other antihypertensive drugs.

The thiazides may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. Thiazides have also been shown to increase responsiveness to tubocurarine.

Lithium, when given with diuretics, reduces renal clearance and increases the risk of lithium toxicity. Refer to the package insert on lithium before use of such concomitant therapy.

Acute renal failure has been reported in a few patients receiving indomethacin and other formulations containing triamterene and hydrochlorothiazide. Caution is therefore advised when administering nonsteroidal anti-inflammatory agents with MAXZIDE.

Drug/Laboratory Test Interactions: Triamterene and quinidine have similar fluorescence spectra; thus MAXZIDE may interfere with the measurement of quinidine.

Pregnancy: Category C: The safe use of MAXZIDE in pregnancy has not been established. Animal reproduction studies have not been conducted with MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg. It is also not known if MAXZIDE can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Thiazides cross the placental barrier and appear in cord blood. The use of thiazides in pregnant women requires that the anticipated benefit be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, pancreatitis, and possibly other adverse reactions which have occurred in the adult. MAXZIDE should be given to a pregnant woman only if clearly needed.

Nursing Mothers: Thiazides appear in breast milk. If the use of MAXZIDE is deemed essential, the patient should stop nursing. Pediatric Use: The safety and effectiveness of MAXZIDE in children has not been established.

ADVERSE REACTIONS: *Side effects observed in association with the use of MAXZIDE include drowsiness and fatigue, insomnia, muscle cramps and weakness, headache, nausea, appetite disturbance, vomiting, diarrhea, constipation, dizziness, decreased sexual performance, shortness of breath and chest pain, dry mouth, depression and anxiety. These adverse reactions are common to other triamterene and hydrochlorothiazide containing products. Other adverse reactions include:*

Hydrochlorothiazide:

Gastrointestinal: anorexia, gastric irritation, cramping, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. Central Nervous System: vertigo, paresthesias, xanthopsia. Hematologic: leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia, megaloblastosis. Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Hypersensitivity: anaphylaxis, purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), fever, respiratory distress including pneumonitis. Other: hyperglycemia, glycosuria, hyperuricemia, restlessness, transient blurred vision.

Triamterene:

Hypersensitivity: anaphylaxis, photosensitivity and rash. Other: Triamterene has been reported in renal stones in association with other calculus materials. Triamterene has been associated with blood dyscrasias. Whenever adverse reactions are moderate to severe, therapy should be reduced or withdrawn.

DOSAGE AND ADMINISTRATION: *The recommended dosage of MAXZIDE is one tablet daily with appropriate monitoring of serum potassium levels (see WARNINGS). Patients receiving 50 mg of hydrochlorothiazide who become hypokalemic may be transferred to MAXZIDE directly. In patients requiring 50 mg of hydrochlorothiazide in whom hypokalemia cannot be risked, therapy may be initiated with MAXZIDE. There is no clinical experience with doses exceeding one tablet daily.*

Clinical studies have shown that patients already taking less bioavailable formulations of triamterene and hydrochlorothiazide (totaling 50-100 mg of hydrochlorothiazide and 100-200 mg of triamterene) may be safely changed to one MAXZIDE™ triamterene 75mg/hydrochlorothiazide 50mg tablet per day; these patients should be monitored clinically and with serum potassium after the transfer.

Follow-Up After Coronary Arterial Reperfusion with Intravenous Streptokinase in Relation to Residual Myocardial Infarct Artery Narrowings

ROLF SCHRÖDER, MD, HANS VÖHRINGER, MD, THOMAS LINDERER, MD, GIANCARLO BIAMINO, MD, THOMAS BRÜGGEMANN, MSc, and ENZ-RÜDIGER V. LEITNER, MD

Short- and long-term changes in residual stenosis of the myocardial infarct-related coronary arteries in patients with successful reperfusion by intravenous streptokinase have not been determined until now. In 15 patients the residual diameter stenosis decreased significantly from 62 ± 9% after 24 hours to 55 ± 13% in the fourth week ($p < 0.005$). Quantitative angiographic analyses in 61 patients with patent infarct-related coronary arteries in the fourth week revealed a mean diameter stenosis of 61 ± 13%. The patients were followed up 34 ± 10 months. Sixteen had elective coronary artery bypass surgery or percutaneous transluminal coronary angioplasty (PTCA). Eighteen without coronary artery bypass surgery or PTCA had undergone repeat angiography after 26 ± 9 months. Twenty-five (41%) have had a residual diameter stenosis greater than 65% in the fourth week. A stenosis greater than 65% was found in: 4 of 5 patients with late reinfarction; 3 of 7 with 1-vessel coronary artery disease and persistent angina, compared with none of 11 with a stenosis less than 65%; 6 of 7, whose silent reocclusion had been found at long-term follow-up compared with 1 of 9 with a residual stenosis less than 65%. In 8 patients with persistent patency of the infarct artery, the stenosis had decreased significantly from 55 ± 6% to 36 ± 12% ($p < 0.005$). Correspondingly, there was a significant improvement in the infarct-related left ventricular wall motion disorders. These data indicate that in patients with less severe residual stenosis in the fourth week after successful intravenous streptokinase the long-term course is relatively uneventful, whereas reocclusion or reinfarction in the same myocardial territory is frequent in patients with a stenosis greater than 65%. PTCA may be advisable in these latter patients.

(Am J Cardiol 1985;55:313–317)

Anatomic studies have shown that a substantial percentage of lesions associated with vessel thrombosis in acute myocardial infarction are moderate in severity.[1,2] Successful thrombolysis can reestablish the coronary anatomy to its conditions before the acute thrombotic occlusion. On the basis of relatively limited information available, there are 2 conflicting attitudes about patients who have undergone successful thrombolytic reperfusion: (1) The affected coronary artery continues to pose the same hazard as before. Therefore, definite treatment requires additional mechanical therapy. (2) If sufficient anticoagulant therapy is given, patients are no different from others with myocardial infarction secondary to coronary artery disease (CAD).[3]

Short- and long-term changes in residual stenosis of the infarct-related coronary artery in patients with successful reperfusion by intravenous streptokinase (i.v. STK) have not been determined until now. In this study tentative answers are formulated on 4 questions: (1) What are the changes in the size of lesions that occur from 24 hours to the fourth week? (2) What is the clinical long-term course in relation to the residual diameter stenosis of the infarct-related coronary artery in the fourth week? (3) Can lesions that are liable to reocclude in the long-term course be identified? (4) To what extent are changes in the left ventricular wall motion disorders dependent from changes in size of coronary

From the Department of Cardiology and Pneumonology, Klinikum Steglitz, Free University Berlin, Berlin, Federal Republic of Germany. Manuscript received August 6, 1984; revised manuscript received October 15, 1984, accepted October 16, 1984.

CABG = coronary artery bypass grafting; PTCA = percutaneous transluminal coronary angioplasty.

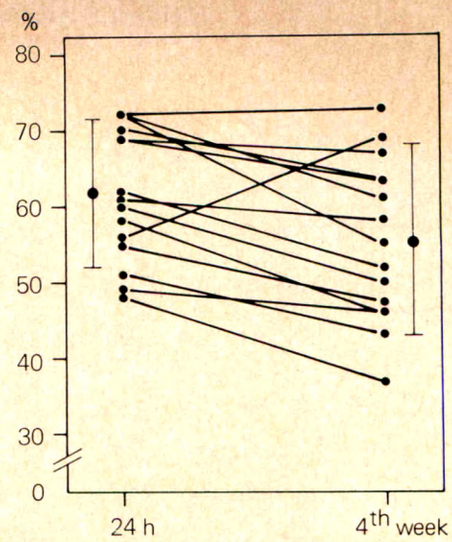

FIGURE 1. Changes in percent diameter stenosis from 24 hours after successful intravenous streptokinase to repeat angiography in the fourth week.

artery lesions occurring during the long-term follow-up?

Methods

Patients: From April 1980 to February 1982, 93 consecutive patients with symptoms and electrocardiographic findings typical of acute myocardial infarction were treated within 6 hours from the onset of chest pain. Forty-nine had a 30-minute i.v. infusion of 500,000 IU of STK and 44 received 1.5 million IU of STK infused within 60 minutes. In all patients 5,000 IU of heparin, 0.5 g of acetylsalicylic acid and 0.25 g of methylprednisolone were injected intravenously before STK. For the next 72 to 96 hours, heparin was infused at a dose sufficient to maintain a partial thromboplastin time at a 2 to 4 times control. Phenprocoumon treatment was initiated on the first or second day and continued for the next 3 weeks. After discharge from the hospital the patients were not treated routinely with anticoagulant therapy or antiplatelet drugs. Further details have been described elsewhere.[4]

In 15 patients with early restoration of coronary blood flow the area and luminal diameter of the most severe stenotic area of the infarct-related coronary artery was measured after 24 hours and in the fourth week. Because of the poor quality of some angiograms, quantitative analyses were not performed immediately after successful lysis. Seventy-five patients underwent angiography during the fourth week after acute myocardial infarction (Table I). Sixty-three patients who revealed a patent infarct-related coronary artery were followed up for a mean of 34 ± 10 months (range 3 to 49). Six patients were followed up until they died.

Nineteen patients who did not undergo coronary artery bypass grafting (CABG) or percutaneous transluminal coronary angioplasty (PTCA) underwent repeat angiography during follow-up. In 18 patients the quality of the angiograms was sufficient for quantitative analysis. There was no patient selection because all patients had been asked to undergo repeat angiography. There was no difference between those who agreed to a repeat study and those who did not with respect to 2- or 3-vessel CAD, impairment of left ventricular function in the fourth week, clinical signs of cardiac failure or angina pectoris.

Quantitative angiographic analysis: The technique of analysis has been described previously.[4,5] Briefly, the most severe stenotic area of the infarct-related coronary artery was analyzed from 2 to 5 cineprojections at end-diastole. Each of these views was projected on a large screen and was carefully traced on a digitizer tablet with as much of the adjacent vessel as could be seen in either view. The mean values of the area and the diameter stenosis were digitally computed for all measurements.

The left ventricular wall motion disorders were calculated from a left ventricular angiogram in a 30° right anterior oblique projection by a computer-constructed polar coordinate system. Excluding the aortic valve plane, the computer divided the silhouettes into 48 segmental radii with equal angles. The end-diastolic and end-systolic contours were superimposed using a fixed reference system. The results were printed out as numerical data and a histogram of percent shortening of the systolic segmental radii. Segmental radii shortening less than one-third of the normal range of systolic shortening in healthy subjects was considered an akinetic segment.

In 2 patients, stenoses could not be measured quantitatively; 1 of them subsequently died, and the other had an uncomplicated course. In the latter patient, the angiogram at repeat study could not be analyzed.

Statistical analysis: Data are expressed as mean ± standard deviation. Paired or unpaired Student *t* tests were applied to the coronary artery lesions and wall motion abnormalities whenever appropriate.

Results

Patency of the infarct-related artery, 24 hours to 4 weeks: Figure 1 shows the changes in the diameter stenosis from 24 hours after successful i.v. lysis to the fourth week. There was a significant decrease, from 62 ± 9% to 55 ± 13% ($p < 0.005$). The corresponding area stenosis decreased from a mean value of 84 ± 8% to 79 ± 13% ($p < 0.01$). None of the 15 patients had reocclusion, but in 1 the diameter stenosis increased to greater than 65% in the fourth week and in 2 it remained above 65%. In 1 of these 3 patients subsequent successful PTCA has been performed. In the other 2, the infarct-related artery was found occluded at repeat angiography several months later.

Clinical long-term course in relation to residual infarct artery lesions: The clinical outcome of the 75 patients with angiography in the fourth week are listed

TABLE II One-Vessel or Multivessel Coronary Artery Disease and Persistent Angina Pectoris in Patients with Uncomplicated Long-Term Course

	1-Vessel CAD	Multivessel CAD
Pt No.	18	18
Stenosis >65%	7	4
Angina	3	5
Angina, stenosis >65%	3 (70, 72, 74%)	1 (71%)

CAD = coronary artery disease.

in Table I. According to angiographic observation during the acute phase (16 patients) or early elevation of serum CK-MB and a significantly earlier peak in the serial serum CK-MB activity curve (53 patients), successful restoration of coronary blood flow was achieved in 69 patients (92%). One patient had a reocclusion after 24 hours, and 5 without angiography in the acute phase had early reinfarction. In these 6 patients the infarct-related coronary artery was occluded in the fourth week.

Of the 63 patients with patent infarct-related arteries in the fourth week, 21 had 1-vessel, 25 had 2-vessel and 17 had 3-vessel CAD. Thirteen patients underwent elective CABG 1.8 ± 1.3 months after the acute infarction; 1 to 5 grafts (mean 3 ± 1) were placed. Two patients had early elective PTCA. One patient underwent late PTCA 38 months after his infarct. Fourteen of these 16 patients had multivessel CAD; all had angina despite intensive medical therapy.

During long-term follow-up 6 patients died from cardiac causes, 4, 5, 10, 15, 16 and 28 months after myocardial infarction, the last 26 months after CABG. Five patients died suddenly and 1 patient died from cardiogenic shock after reinfarction. Five reinfarctions occurred at the site of the previous infarct, 5 and 6 weeks as well as 6, 26 and 38 months after the first infarction.

Thirty-seven patients had a clinically uncomplicated long-term course. When present, angina was sufficiently controlled by medical therapy. However, during exercise electrocardiography 27 ± 7 months after infarction and interrupted medical therapy, 8 patients experienced angina at a mean workload of 1.2 ± 0.3 (0.75 to 1.7) w/kg body weight (Table II).

Figure 2 lists the individual data, mean and standard deviations of the diameter stenosis of the infarct-related artery measured in the fourth week after successful i.v. STK. For 1 patient who subsequently died and 1 with an uncomplicated course, quantitative analysis could not be performed. The average residual diameter stenosis in 61 patients was 61 ± 13%.

In the 16 patients who underwent CABG or PTCA, the mean diameter stenosis was 67 ± 9%. Eight of these 16 patients had a stenosis greater than 65%. In patients who had a reinfarction during follow-up, the diameter stenosis in 4 of 5 was greater than 65%.

Thirty-six patients with clinically uncomplicated long-term follow-up had a residual diameter stenosis of 58 ± 13%. Eighteen patients had 1-vessel CAD, 7 of whom had a residual diameter stenosis greater than 65%

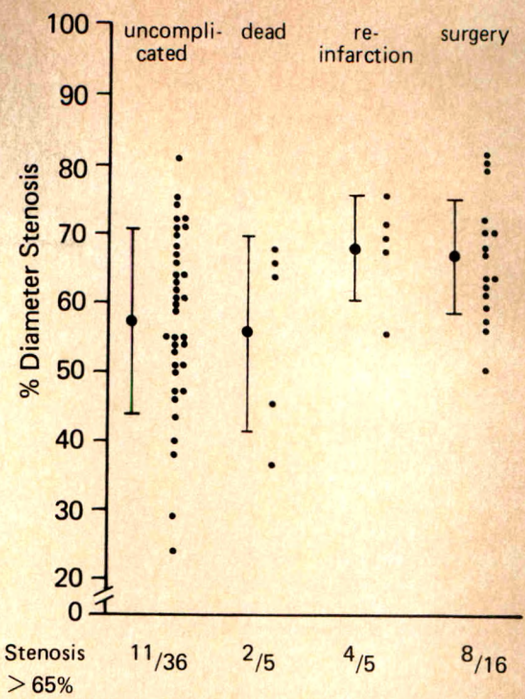

FIGURE 2. Individual data and mean ± standard deviation of diameter stenosis of the infarct artery in the fourth week in relation to the long-term course.

of the infarct-related coronary artery. After discontinuation of medical treatment, 3 of these 7 patients had angina on exertion, whereas none of 11 with a residual diameter stenosis less than 65% had angina (Table II).

In 5 patients with late cardiac death, the diameter stenosis in the fourth week did not differ from that in patients with an uncomplicated course. However, all patients who subsequently died had multivessel CAD and severe left ventricular impairment. The ejection fraction was 39 ± 16%, compared with 60 ± 12% in patients who survived.

Patency of the infarct-related vessel, chronic stage, fourth week to follow-up: Figure 3 shows the changes in diameter stenosis from the fourth week to repeat study 26 ± 9 months later in 18 patients who had no CABG or PTCA. In 2 patients with longer, extended and subtotal occlusion and opacification of the peripheral parts of the vessel mostly through collateral vessels (i.e., functional occlusion), the arteries were considered occluded.

Eight patients had a diameter stenosis greater than 65% in the fourth week. In 6 patients, the infarct artery was occluded, although there had been no clinical signs of reinfarction. Two patients have had reinfarctions. One patient with a high-grade stenosis of a diagonal branch underwent repeat study after an uneventful course of 27 months, and the coronary artery lesion was almost the same. The patient was free of symptoms and had a negative exercise electrocardiogram up to 200 W. Ten months later he had a reinfarction, which was successfully treated with i.v. STK. Angiography the next day showed that the infarct artery was patent, but the size of the residual diameter stenosis was 72%,

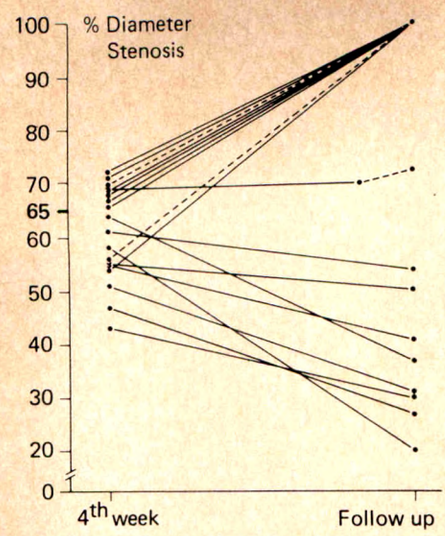

FIGURE 3. Changes in diameter stenosis from the fourth week to repeat study 26 ± 9 months later in patients without coronary artery bypass surgery or percutaneous transluminal coronary angioplasty. **Broken lines** represent patients who had a reinfarction in the interval.

compared with 69% 10 months before. Successful PTCA was performed in the same setting.

Ten patients had a residual diameter stenosis of less than 65% in the fourth week after the acute event. In 8, during follow-up, the stenosis decreased significantly from a mean value of 55 ± 6% to 36 ± 12% ($p < 0.005$). In 2 patients the infarct-related coronary artery was occluded; of these patients 1 had had a reinfarction. Both patients had multivessel CAD and more than 1 stenosis of the infarct-related coronary artery. CABG had been recommended to both patients, but both had refused.

Changes in left ventricular wall motion disorders, chronic stage, fourth week to follow-up: Figure 4 shows the changes in the left ventricular function during follow-up in patients with a diameter stenosis less than 65% in the fourth week. One patient with 3-vessel CAD and a second infarction different from the localization of the previous infarct is excluded. There was a decrease in the infarct-related number of akinetic segments from 7.2 ± 5 to 4.2 ± 7 ($p < 0.05$). In the 7 patients with patent infarct-related coronary arteries, the number of akinetic segments decreased from 5.9 ± 3 to 0.7 ± 1 ($p < 0.005$). In these 7 patients the ejection fraction increased from 56 ± 7 to 63 ± 9% ($p < 0.05$).

Figure 5 shows the changes in the number of akinetic segments in the 8 patients with a diameter stenosis greater than 65% in the fourth week. On the average, there was no change in the number of akinetic segments (4.3 ± 6 to 3.8 ± 4). Although their infarct-related coronary arteries were found occluded during follow-up, 3 showed considerable improvement, probably because sufficient collateral flow had developed.

Discussion

The appearance of a lesion immediately after reperfusion with intracoronary (i.c.) STK does not reflect the eventual size of the underlying fixed lesion. Further increase in the luminal diameter after 1 or more weeks compared with immediate post-i.c. STK has been shown.[6–9] Our findings in 15 patients with successful i.v. STK indicate that the extent of residual stenosis may substantially decrease even after 24 hours. In only 3 of 15 patients was there no decrease or increase in the remaining stenosis of the infarct-related coronary artery in the fourth week compared with that 24 hours after the acute event. Possible reasons for late changes in the size of stenosis after reperfusion with STK were thoroughly discussed by Harrison et al.[9]

In the fourth week after successful i.v. STK, quantitative analysis of the infarct-related coronary artery revealed a residual diameter stenosis of 61 ± 13%. This finding is in keeping with the results obtained by quantitative angiographic analysis 2 weeks after successful i.c. STK.[8,9] However, more severe residual stenosis of the recanalized coronary artery by i.c. STK have

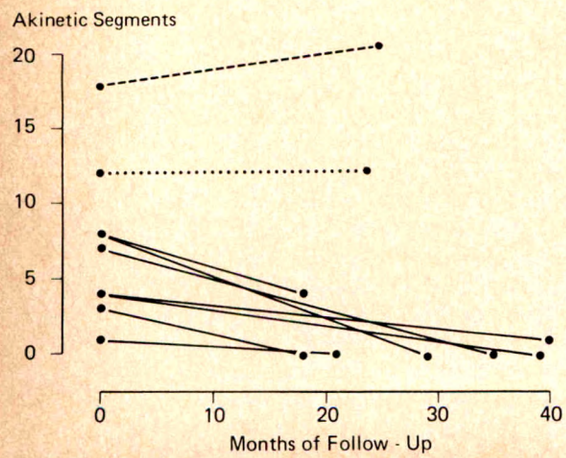

FIGURE 4. Changes in number of akinetic segments during follow-up in patients with a diameter stenosis less than 65% in the fourth week. **Broken line** indicates patient who had reinfarction in the interval. **Dotted line** indicates patient whose infarct-related artery was found to be occluded ("silent occlusion").

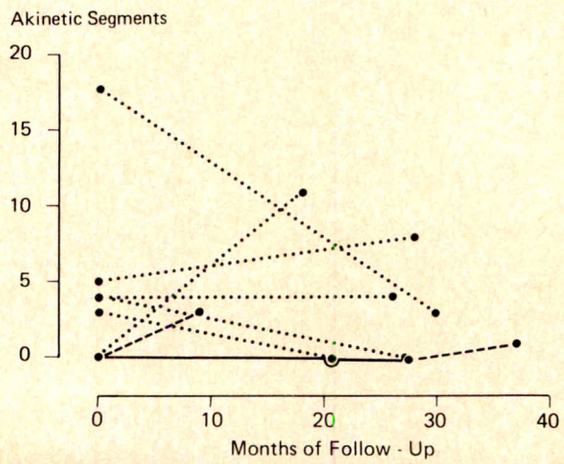

FIGURE 5. Changes in the number of akinetic segments during follow-up in patients with a diameter stenosis greater than 65% in the fourth week. **Broken line** indicates patient who had reinfarction in the interval. **Dotted line** indicates patients whose infarct-related artery was occluded ("silent occlusion").

been reported.[10,11] These reports are based on subjective interpretation of the stenotic lesions. Overestimation and excessive variations by intra- or interobserver error have been reported. Some reports suggest that the traditional analysis of coronary angiograms is inadequate for determining significance of coronary stenosis.[8,9] When histologic sections of patients with transmural acute myocardial infarction and coronary artery thrombi[12] are compared with cross-sectional areas derived from diameter measurements after lysis, the quantitative angiographic results from Serruys et al,[8] Harrison et al,[9] and ours in vivo are consistent with the histologic findings.

The optimal management course after successful thrombolytic therapy has not been defined. An incidence of more than 20% of reinfarctions and late reocclusions after successful i.c. STK treatment has been reported.[8,13–15] Therefore, additional PTCA immediately after i.c. STK[8,15,16] or CABG[17,18] has been advocated. However, the observation that the extent of residual stenosis may decrease spontaneously and that the early reocclusion rate after PTCA may be as high as 20%[19] emphasizes that the true value of additional PTCA remains to be assessed.

In patients with high-dose i.v. STK of brief duration, early reinfarction rates tended to be lower.[4,20–22] The early reocclusion and reinfarction rates may be in the same order as in patients with i.c. STK and additional PTCA.[8,9,19,23,24] However, the long-term course tended to be more complicated in patients with a more severe residual stenosis. Four of 5 patients who sustained a late reinfarction had a residual diameter stenosis greater than 65% in the fourth week. Three of 7 patients with 1-vessel CAD and a stenosis greater than 65% had persistent angina pectoris on exertion; none of 11 had less severe stenosis.

Although our results are limited by the small number of patients studied, it appears that vessels with a residual diameter stenosis greater than 65% in the fourth week frequently reocclude during long-term follow-up. Late reocclusion may not imply reinfarction or worsening of the left ventricular function. On the contrary, there may be considerable improvement. However, even retrospectively we were unable to predict the particular patient's risk.

Value of Radionuclide Angiography for Predicting Specific Cardiac Events After Acute Myocardial Infarction

KENNETH G. MORRIS, MD, SEBASTIAN T. PALMERI, MD, ROBERT M. CALIFF, MD, RAY A. McKINNIS, PhD, MICHAEL B. HIGGINBOTHAM, MB, R. EDWARD COLEMAN, MD, and FREDERICK R. COBB, MD

The value of rest and exercise radionuclide angiography (RNA) for predicting specific events including death, recurrent acute myocardial infarction (AMI), coronary care unit readmission for unstable chest pain, and medically refractory angina after AMI was studied in 106 consecutive survivors of AMI. Analysis of the RNA variables using the Cox proportional hazards regression model yielded significant associations of the time to death with ejection fraction at rest and during exercise (χ^2 = 11.1 and 14.0, respectively). Both variables added significant prognostic information to the clinical assessment (χ^2 = 4.3 and 5.7, respectively). The change in ejection fraction from rest to exercise predicted the time to coronary artery bypass grafting for medically refractory angina before (χ^2 = 21.0) and after (χ^2 = 13.2) adjustment for the clinical descriptors, but did not predict death or other nonfatal events. Significant correlations were found between RNA variables and a variety of clinical descriptors previously reported to have prognostic significance. Clinical and RNA variables that are measures of left ventricular function were predictive of subsequent mortality, whereas those that reflect residual potentially ischemic myocardium were predictive of subsequent nonfatal ischemic events. Rest and exercise RNA after AMI provides significant prognostic information regarding specific events during follow-up independent of that provided by clinical assessment.

(Am J Cardiol 1985;55:318–324)

A variety of clinical and laboratory variables have prognostic significance in survivors of acute myocardial infarction (AMI). The underlying pathophysiology reflected by these variables appears to be predominantly the severity of left ventricular (LV) dysfunction produced by AMI or the presence of potentially ischemic myocardium. Variables such as Killip class, cardiomegaly, infarct location and exercise time that correlate with the severity of LV dysfunction after AMI have been reported to have prognostic significance.[1–8] Studies have shown that among clinical and contrast angiographic variables, ejection fraction (EF) at rest, a direct measure of LV function, is the most important predictor of mortality after AMI.[9,10] Other prognostic variables such as recurrent angina pectoris, exercise stress testing variables,[11–13] and the angiographic severity of coronary artery disease (CAD)[10] are indicators of myocardium that may become ischemic. Radionuclide angiography is a noninvasive method of evaluating LV function at rest and exercise,[14] and is more sensitive than ST-segment changes for detecting significant CAD.[15] Thus, rest and exercise RNA is an attractive procedure for risk assessment after AMI because it provides noninvasive measurements of both the severity of LV dysfunction and the presence of potentially ischemic myocardium.

The purpose of the present study was to ascertain the relation of specific rest and exercise RNA measurements with specific follow-up events and to determine their value added to other clinical variables for predicting mortality, recurrent AMI, and unstable or medically refractory angina in follow-up in a prospective study of survivors of AMI.

NYHA class CHF	3 wks post-MI	72	22	10	2

CHF = congestive heart failure; MI = myocardial infarction; NYHA = New York Heart Association.

Methods

Patients: A prospective consecutive series of 165 patients admitted to the coronary care unit of the Durham Veterans Administration Medical Center with documented myocardial infarction manifest by chest pain and positive myocardial creatine kinase isoenzymes was evaluated for this study. Seventeen patients died within 21 days of AMI and were excluded from the study group. Eighteen patients were excluded from the study because of valvular heart disease, chronic renal insufficiency, metastatic malignancy or other serious comorbid disease. Fifteen patients refused participation in the study. Nine patients could not exercise because of severe congestive heart failure, lower extremity amputation or unstable pain. One hundred six patients constituted the study group.

Study protocol: The study protocol consisted of RNA at rest and during upright bicycle exercise 3 weeks after AMI. Exercise was performed on a bicycle ergometer in the postabsorptive state. Beta-adrenergic blocking drugs were tapered and discontinued 48 hours before study. Nitrates were withheld 6 hours before study. Exercise was initiated at 100 or 200 kpm and increased by 100 kpm each minute. Heart rhythm was monitored continuously and standard limb leads and V_5 and V_6 electrocardiograms were recorded at rest and at each minute of exercise. Exercise endpoints were a maximal heart rate of 120 beats/min, chest pain, significant ST depression or severe fatigue. RNA was performed in the sitting position before exercise and at peak exercise. Clinical assessment included New York Heart Association (NYHA) functional class for angina and congestive heart failure and ST-segment changes and chest pain during exercise.

Radionuclide angiography: Gated equilibrium RNAs were acquired over $1\frac{1}{2}$ to 2 minutes after in vivo red cell labeling with technetium-99m using a Siemens L.E.M. gamma camera and an r-wave-triggered gate interfaced to an MDS modumed or A^2 computer system. Data were analyzed in a 64 × 64 matrix as twenty-eight 100,000 count frames. A semiautomated edge detection algorithm (A2MUGE, MDS) was used to outline the LV region of interest for each frame. A varying region-of-interest technique was then used for construction of a volume curve after background correction for calculation of the EF. Wall motion abnormalities were evaluated qualitatively by consensus from an endless loop display. Each RNA was divided into septal, inferoapical and posterolateral segments and each was scored as 0 (normal), 1 (mild hypokinesia), 2 (severe hypokinesia), 3 (akinesia) and 4 (dyskinesia). Patients with higher scores at exercise than at rest in any region were considered to have exercise-induced abnormalities.

Therapy and follow-up: The results of RNA testing were not reported to the physicians treating the patients or used for therapeutic decision-making. Beta-adrenergic blocking agents were not used prophylactically, but were given for significant angina. Patients with refractory angina or positive treadmill stress tests at low workloads (stage I or II, Bruce protocol) underwent coronary angiography. Only patients with refractory NYHA class III or IV angina or left main coronary stenosis greater than 50% underwent bypass grafting.

2° AVB = second-degree atrioventricular block; PVCs = premature ventricular complexes.

Two patients had significant left main CAD but also had class IV angina.

Patients were followed either by clinic appointment or by telephone with regard to mortality, functional class for angina pectoris, hospitalization for myocardial infarction or unstable angina, and coronary artery bypass grafting (CABG) for disabling angina refractory to medical therapy. The minimal duration of follow-up was 24 months. All recurrent infarcts were documented by new electrocardiographic Q waves or enzyme measurements. Patients were readmitted to the coronary care unit for unstable angina, defined as recurrent episodes of prolonged chest pain or a marked progression in the frequency and severity of their chest pain syndrome.

Data analysis: The strengths of associations between RNA measurements and individual clinical variables were determined using the Spearman rank correlation coefficient.

The value of rest EF, exercise EF, the change in EF from rest to exercise, and exercise-induced wall motion changes was analyzed for predicting 4 specific events in follow-up. These included death, recurrent nonfatal infarction, CABG for medically refractory disabling angina pectoris, and admission to the coronary care unit for unstable angina. Because the pathophysiology of the various events may be different, each event was analyzed separately and no events were combined for analysis. When nonfatal events were analyzed the follow-up of patients who died was censored at the time of death.

For all prognostic analyses, associations between each RNA variable and the time to an event were determined using Breslow's formulation of the Cox proportional hazards regression model.[16,17] The log likelihood ratio chi-square statistic of the univariable model was first used to assess the significance of the relation between each RNA variable and the time to each event. This analysis was then extended to determine whether RNA measurements contributed information beyond that available using clinical parameters. For this analysis, a 2-step model was used in which the combined significance of the clinical variables was considered first in the proportional hazards regression model; the added value of the

RNA variable of interest was then examined. To determine the statistical significance of the added contribution of each RNA variable, the difference in model log likelihood ratio chi-square using the clinical variables alone was compared with the chi-square value using both the clinical variables and the RNA variables. The clinical variables that were used included age, previous infarction, infarct location, worst Killip class, infarct extension, cardiomegaly, ventricular arrhythmias and atrial tachyarrhythmias during the acute infarct period, NYHA functional class for angina and congestive heart failure, and the occurrence of ST depression (at least 0.1 mV) with exercise. Atrial tachyarrhythmias were analyzed together as a single dichotomous variable. Ventricular arrhythmias were graded as an index with the following weight: 2 points for ventricular fibrillation, 1 point for ventricular tachycardia, ½ point for at least 6 premature ventricular contractions per minute after the first 48 hours and ¼ point for at least 6 premature ventricular contractions per minute in the first 48 hours. Because of the small number of coronary artery bypass procedures during the follow-up period, only the most significant clinical variables, i.e., worst Killip class, infarct location, functional class for angina, and ST depression with exercise, were included in the adjusted models for medically refractory angina.

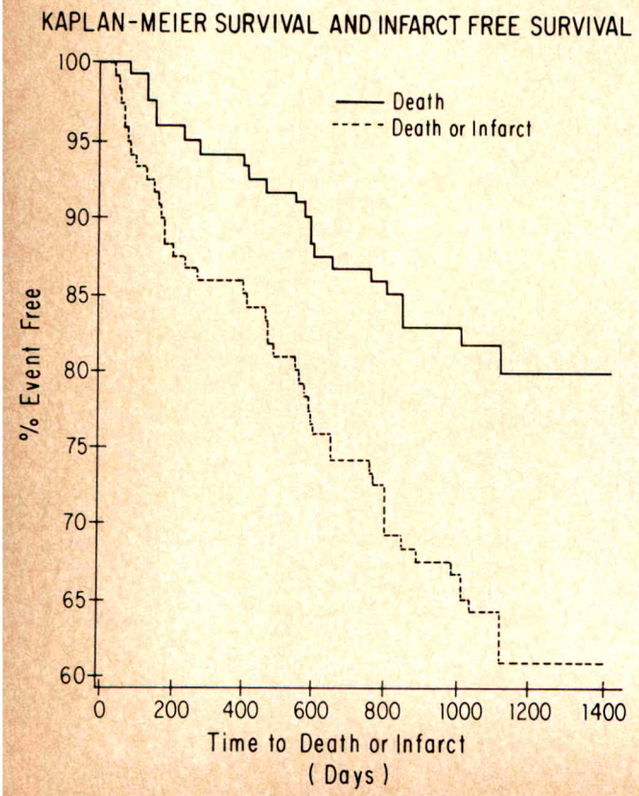

FIGURE 1. Life-table survival and infarct-free survival of the patient population.

Results

Baseline characteristics: The 106 patients (105 men, 1 woman) studied were 31 to 84 years old (mean 56). The electrocardiographic location of AMI was anterior in 31, inferior in 40, inferior and anterior in 2, undetermined in 1 (with left bundle branch block), and "subendocardial," i.e., not accompanied by new Q waves, in 32; 37 had a history of AMI. The frequency of other selected baseline characteristics of the population is summarized in Tables I and II.

Clinical outcomes: Figure 1 shows the rate of cardiac deaths and recurrent AMI. By 1 year of follow-up, 15% of patients had either died or sustained a recurrent AMI and by 2 years of follow-up 27% had 1 of these major cardiac events. During the follow-up period, 24 patients died. Fifteen deaths were sudden, 2 deaths were associated with progressive congestive heart failure, 4 occurred within a few days of a documented recurrent AMI, 2 occurred in hospital with heart failure or ventricular fibrillation shortly after a prolonged episode of chest pain and 1 patient had a fatal cerebrovascular accident. During the same period of follow-up 20 patients had recurrent nonfatal AMI, 21 were readmitted to the coronary care unit with unstable chest pain and 10 underwent CABG for disabling medically refractory angina pectoris. Thirty-eight patients had 1 or more of these nonfatal events.

Relation of radionuclide angiographic variables to clinical descriptors: Table III is a summary of correlations between the RNA variables and selected clinical variables that have been reported to be of prognostic significance. In general, rest and exercise EF correlated inversely with variables that reflect diminished LV function, such as history of infarction, anterior infarction, Killip class, cardiomegaly and the functional

class for congestive heart failure. The change in EF from rest to exercise correlated inversely with the occurrence of exercise-induced ST-segment depression. Exercise-induced wall motion abnormalities did not correlate with any clinical variable.

Predictors of mortality: Table IV is a summary of the results of Cox model analysis of the relation among the RNA and clinical variables and the time to each event. Both rest and exercise EF were correlated inversely with subsequent mortality; exercise EF had a higher chi-square value (14.0, $p < 0.001$) than the rest value ($\chi^2 = 11.1$, $p < 0.001$). When the aggregate significance of only the clinical variables was considered in a multivariable model, a chi-square value of 24.9 was obtained. However, the 12 degrees of freedom (d.f.) necessary in this multivariable model reduced the level of significance ($p = 0.02$). Thus, both RNA EF measurements achieved a higher level of significance than the combination of clinical variables. Worst Killip class and history of infarction were the most significant clinical variables; chi-square values were 5.23 and 3.83 (1 d.f.), respectively, after adjustment for the other clinical descriptors. When the RNA variables were examined to determine the amount of prognostic information, they provided beyond that contained in the clinical data, both exercise and rest EF yielded significant independent prognostic information ($\chi^2 = 5.7$ and 4.3, respectively). When both rest and exercise EF were included in a bivariable model, only the exercise value remained significant.

To further illustrate the added value of the RNA over the clinical variables, the patients were separated into high- and low-risk groups on the basis of clinical characteristics. Patients with ventricular fibrillation or tachycardia, Killip class III or IV, supraventricular tachyarrhythmia or infarct extension were classified as high risk. Among the 80 patients with at least 1 of these high risk indicators, mortality was 48% (14 of 29) in patients with exercise EF of 40% or less, compared with 10% (5 of 51) with exercise EF of more than 40%. Of the 26 patients considered to be at low risk by the absence of any of these clinical criteria, 5 had an exercise EF of 40% or less and 2 of these patients (40%) died during follow-up, compared to only 14% (3 of 21) with exercise EF more than 40%.

The change in EF from rest to exercise was not significantly associated with the time to death. Since previous studies have demonstrated an inverse relation between rest EF and the change in EF with exercise,[18,19] patients with EF less than 30% were excluded from a second analysis in an attempt to improve the predictive value of the change in EF with exercise. Among the 86 patients with a rest EF of more than 30%, 14 died during the follow-up period; however, the change in EF from rest to exercise was not associated with the time to death, even in this subgroup of patients. The occurrence of exercise-induced wall motion abnormalities, another variable related to myocardial ischemia, also was not significantly associated with the time to death.

The 2-year mortality predicted by the Cox regression model from exercise EF alone is shown in Figure 2. As EF fell below 45%, mortality increased dramatically. Thus, the expected mortality at 2 years was 11% with

n = number of events; χ^2 = likelihood ratio chi-square with 1 degree of freedom except where indicated. (The multivariable χ^2 for each parameter is an assessment of prognostic significance, adjusted for clinical variables.); other abbreviations as in Table III.

* $p \leq 0.05$.

an exercise EF of 50%, 29% with an exercise EF of 30% and 56% with an exercise EF of 15%. Figure 3 shows the same relation in a different fashion, by comparing the Kaplan-Meier survival curve of patients with an exercise EF less than 40% to the survival curve of patients with an exercise EF of at least 40%.

Nonfatal infarction: The time to nonfatal AMI was associated only with the development of exercise-induced wall motion abnormalities ($\chi^2 = 4.1$). After adjustment for the 12 clinical descriptors, this relation was not statistically significant. The time to nonfatal AMI was not significantly associated with the clinical variables.

Unstable angina: The time to coronary care unit admission for unstable chest pain was not associated with any of the RNA variables. The clinical variables were significantly associated with subsequent readmission of the coronary care unit for unstable angina ($\chi^2 = 24.5$, 12 d.f., $p = 0.02$). NYHA classes for angina and congestive heart failure 3 weeks after infarction were the most significant variables (adjusted χ^2 [1 d.f.] = 5.22 [$p = 0.02$] and 8.51 [$p = 0.004$], respectively).

Disabling refractory angina: The time to CABG for disabling refractory angina was highly associated with the change in EF from rest to exercise before and after adjustment for clinical descriptors; the chi-square values (1 d.f.) were 21.08 and 13.19, respectively. The time to CABG for medically refractory angina was significantly associated with exercise-induced wall motion abnormalities, but the relation was not significant after adjustment for the clinical variables. The 4 clinical variables also were not significantly associated with this endpoint.

Discussion

In this study, rest and exercise EF were the most important predictors of subsequent mortality among the variables studied. EF during exercise was the most potent predictor of mortality. Exercise EF is the sum of the rest EF and the change in EF during exercise and thus reflects the amount of infarcted myocardium as well as the myocardium at risk for further ischemia or AMI. Exercise EF contained all of the prognostic information present in the rest value. The rigorous statistical analysis shows that both variables provided prognostic information beyond that available from clinical assessment. Furthermore, several clinical variables that have been associated with increased mortality in previous studies also correlated with a reduced EF. These included variables such as worst Killip class, NYHA functional class for congestive heart failure, cardiomegaly, and infarct location, which might be anticipated to relate to the severity of LV dysfunction. The prognostic value of certain clinical variables thus appears to result from their relation to the severity of LV dysfunction.

The 2 RNA variables most specifically related to exercise-induced ischemia, the change in EF from rest to exercise and exercise-induced wall motion abnormalities, were not significant univariate predictors of subsequent mortality. Several points should be considered in interpreting the lack of a relation in this study between the change in EF with exercise and subsequent mortality. We observed that in a population of patients with CAD the change in EF with exercise is inversely related to the rest EF.[18,19] Consequently, subjects with normal rest function have the highest likelihood of

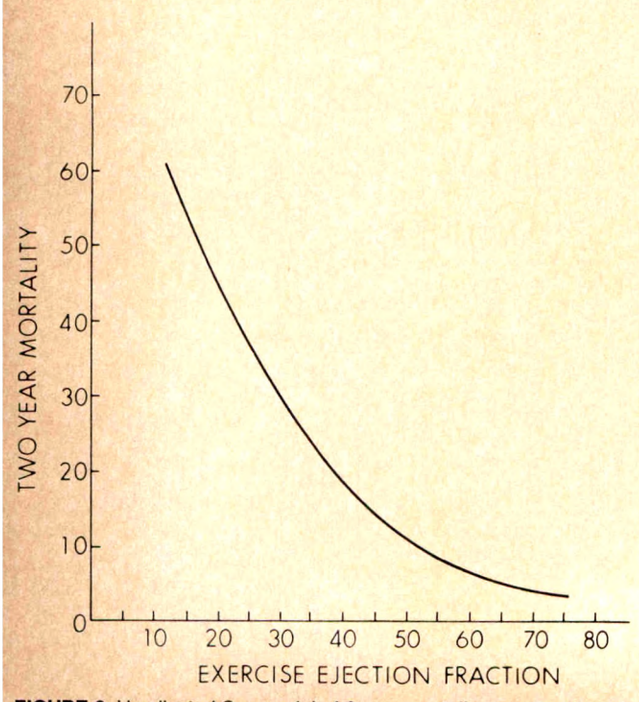

FIGURE 2. Unadjusted Cox model of 2-year mortality as a function of exercise ejection fraction.

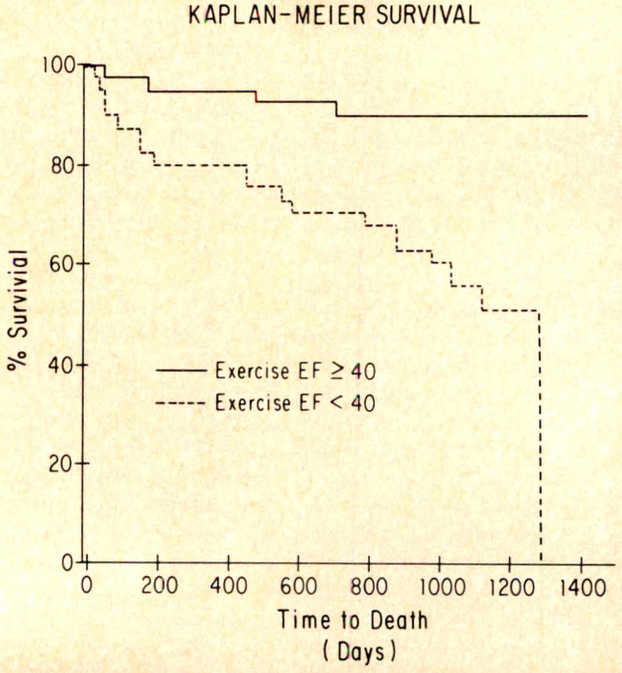

FIGURE 3. Life-table survival of patient population by exercise ejection fraction (EF). EF ≥ 40, n = 72; EF <40, n = 34.

showing a decrease in EF with exercise, but a low mortality. However, subjects with a severe reduction in rest EF often show either no change or an increase in EF during exercise, but a high mortality in the follow-up period. Thus, it is not inconsistent that the change in EF in the total population is not an independent predictor of mortality. Another factor that may influence the predictive ability of a change in EF during exercise is that a decrease in EF of 15% may have different significance when it decreases from 60% to 45% than when it decreases from 45% to 30%. In the latter case the compromise of LV performance produced by the combination of the prior infarction and exercise-induced ischemia is much greater than the former, and this combined effect is important prognostically. These observations are consistent with the hypothesis that the severity of LV dysfunction produced by the AMI is the most important predictor of survival, but that myocardial dysfunction caused by ischemia during exercise provides additional but not independent prognostic information concerning mortality.

While mortality appears to be related primarily to the severity of LV dysfunction and secondarily to the presence of residual myocardial ischemia, certain nonfatal ischemic events may be expected to correlate primarily with RNA indexes of ischemia such as the change in EF from rest to exercise and the occurrence of exercise-induced wall motion abnormalities. Neither the clinical variables nor the RNA parameters were predictive of recurrent infarction. Exercise-induced wall motion abnormality was the only RNA variable that was related to recurrent infarction, but this relation was of only borderline univariate significance.

Admission to the coronary care unit for unstable chest pain during the follow-up period was predicted by the clinical variables reflecting recurrent angina early in the postinfarction course. The absence of any relation between RNA variables and coronary care unit hospitalization for chest pain was surprising but may be due to the heterogeneous nature of clinical chest pain syndromes resulting in rehospitalization after infarction.

The relatively small number of patients undergoing CABG reflects the practice pattern at the Veterans Administration Medical Center during the period of the study; patients were selected for surgery primarily for angina refractory to medical therapy. RNA results were not reported and thus were not used as a criteria for surgical therapy. The RNA variables that were associated with this event were all indexes of exercise-induced ischemia. The change in EF from rest to exercise demonstrated the highest correlation with medically refractory angina. This variable was also correlated with the occurrence of exercise-induced ST depression, the only other prognostic variable in the data set other than the functional class for angina which might reflect residual jeopardized myocardium.

The results of this study are consistent with those of previous studies that suggest that rest EF as measured by RNA is related to subsequent mortality in the postinfarction population.[20–24] With the exception of the Multicenter Postinfarction Research Group, none of these studies had enough deaths to analyze the relation of EF to mortality in a detailed fashion. Most of these studies also analyzed EF as a dichotomous variable, which reduces its apparent prognostic significance.[25] The Multicenter Postinfarction Research Group Study[24] showed that mortality is related to rest EF in a continuous fashion. The present study demonstrates similar relations for both rest and exercise EF.

Corbett et al[26,27] analyzed the prognostic value of RNA after AMI in terms of combined cardiac events; mortality was not studied as a specific event. They observed that the change in EF from rest to exercise was the most important prognostic variable for combined cardiac events. Of the 74 combined cardiac events, 34 were limiting or refractory angina, 17 were persistent heart failure, 14 were recurrent AMI and 9 were deaths. They also reported that exercise EF correlated with 41 "major events," which included the deaths. However, it cannot be determined from the analysis which specific cardiac events were related to each RNA variable. DeWhurst and Muir[28] reported that an EF less than 35% or a decrease in EF with exercise greater than 5% occurred in 15 of the 17 patients who died in their series. They also found that the change in EF with exercise was associated specifically with subsequent postinfarction angina. In contrast to the present study, neither of the previous studies used rigorous statistical methods to determine the added value of RNA beyond clinical assessment.

Prognostic Significance of Precordial ST-Segment Depression During Inferior Acute Myocardial Infarction

MARK A. HLATKY, MD, ROBERT M. CALIFF, MD, KERRY L. LEE, PhD, DAVID B. PRYOR, MD, GALEN S. WAGNER, MD, and ROBERT A. ROSATI, MD

To study the mechanism and prognostic importance of precordial ST-segment depression during inferior acute myocardial infarction, 162 patients admitted during 1969 through 1982 were identified. Patients with ST depression in leads V_1, V_2 and V_3 had significantly larger infarctions as assessed by a QRS scoring system. Hospital mortality was 4% (3 of 75) among patients without ST depression, and 13% (11 of 87) in patients with ST depression. The relation between the amount of ST depression and hospital mortality was significant ($p < 0.001$ by logistic regression), and remained significant ($p < 0.003$) after adjusting for other potentially prognostic factors. Among patients discharged from the hospital, the 5-year survival was 92% in those without precordial ST depression and 80% in those with precordial ST depression ($p = 0.058$ by the Cox model). Precordial ST-segment depression on the admission electrocardiogram during an inferior acute myocardial infarction indicates a larger infarction, predicts a higher hospital mortality and suggests a worse long-term prognosis after discharge.

(Am J Cardiol 1985;55:325–329)

The significance of the precordial ST-segment depression that sometimes accompanies inferior acute myocardial infarction (AMI) remains controversial. This reciprocal change may result passively from inferior ST-segment elevation,[1] but several studies suggest that it may represent an active, primary process. In particular, it may indicate posterior epicardial injury and a larger area of jeopardized myocardium, consistent with the higher peak levels of creatine kinase and lower ejection fractions found in such patients.[2–6] Alternatively, this electrocardiographic (ECG) change may arise from anterior wall ischemia,[7] since some studies have found an association with left anterior descending stenosis,[8,9] although others have not.[4,10] Thus, precordial ST depression during inferior AMI may be a benign ECG finding of little clinical importance, or it may be a valuable marker of patients with increased risk.

The major goal of this study was to define the prognostic significance of the precordial ST-segment depression in the admission electrocardiogram of patients with inferior AMI. Since many other factors also affect prognosis after AMI, multivariable analyses were used to determine if precordial ST changes contribute independent information. The mechanism of precordial ST-segment changes was also investigated by identifying the location and estimating the extent of the acute infarct, as indicated by the QRS changes.

Methods

Since January 1969, data from all patients admitted to the Duke University cardiac care unit with AMI have been prospectively entered into a computer database, described in detail elsewhere.[11] Information on 52 clinical variables is recorded daily and stored. Patients have been followed after discharge at 6 months, at 1 year and annually thereafter.

All patients who met the following criteria were identified: a history of prolonged chest pain, characteristic changes in serum enzymes, and development of a Q wave 0.03 second or longer in lead aVF. Patients admitted to the cardiac care unit by interward or interhospital transfer were excluded. Patients with either history or ECG evidence of previous MI or ECG criteria for ventricular hypertrophy or bundle branch block were also excluded, as were those with ST elevation in leads V_1, V_2 or V_3. Patients with some ST-segment elevation in leads V_4, V_5 and V_6 associated with ST depression in V_1, V_2

and V_3 were accepted, however, if the amount of this ST elevation was less than that in inferior leads II, III and aVF, since this was considered indicative of inferoapical involvement.[12,13] Patients seen after June 1982 were excluded to ensure at least 1 year of follow-up for each patient.

Admission electrocardiograms were reviewed by cardiologists blinded to the follow-up information. ST-segment deviation was identified by a non-isoelectric J point. The amount and direction of any ST-segment deviation from the isoelectric baseline was measured at 0.08 second after the J point to the nearest 0.05 mV in all 12 leads. For purposes of analysis, the amount of ST-segment depression in leads V_1, V_2 and V_3 was summed.

Prognosis: The effect of precordial ST depression in V_1, V_2 and V_3 was examined for both short-term prognosis (hospital mortality) and long-term prognosis. To use all the information available, ST depression was used in statistical tests as a continuous variable rather than a categorical "present" or "absent." [14] For ease in describing the findings, however, the patients were divided into 2 groups. Patients in group 1 had less than 0.05 mV of ST depression in each of leads V_1, V_2 and V_3, and the remaining patients formed group 2.

The logistic regression model was used to test whether the sum of precordial ST-segment depression in leads V_1, V_2 and V_3 was predictive of hospital survival. Breslow's formulation[15] of the Cox proportional hazards model[16] was used to test whether the sum of precordial ST depression was predictive of long-term prognosis in hospital survivors. Initially, univariable analyses were performed. Subsequently, multivariable analyses were performed to test whether the sum of precordial ST-segment depression added significantly to the prognostic information provided by other factors.

The logistic regression model was also used to test whether the sum of precordial ST-segment depression in leads V_1, V_2 and V_3 was predictive of urgent complications during hospitalization. The occurrence of 1 or more of the following was considered an urgent complication[17]: ventricular tachycardia, ventricular fibrillation, persistent hypotension, Killip class III or IV, or reinfarction. Ventricular tachycardia was defined as 3 or more beats of ventricular origin at a rate of 100 beats/min or greater. Persistent hypotension was defined as a systolic blood pressure less than 90 mm Hg lasting for 1 hour or more.

Comparison of QRS changes: The pathogenesis of precordial ST depression was investigated by using the predischarge electrocardiogram to judge the size and extent of infarction by means of the QRS scoring system.[12,13] This scoring system consists of criteria regarding Q- or R-wave duration and amplitude ratios for each of 10 leads (I, II, aVL, aVF and V_1 through V_6). The accuracy of this method in predicting the size and location of myocardial necrosis has been validated.[12,13]

We hypothesized that (1) if precordial ST depression were the result of posterior injury, patients with this finding should show QRS changes of posterior infarction more frequently; and (2) if precordial ST depression were due to anterior subendocardial injury, patients with this finding should develop QRS changes of anterior infarction more frequently. To test the first hypothesis, the number of QRS points in leads V_1 and V_2 indicative of posterior wall damage developed by patients without precordial ST depression (group 1) was compared with the number of posterior wall QRS points developed by patients with precordial ST depression (group 2). Similarly, to test the second hypothesis, the number of anterior wall QRS points in leads V_1 through V_4 (development of Q waves or R-wave loss) developed by group 1 patients was compared to those developed by group 2 patients. Statistical significance was assessed by means of nonparametric 1-way analysis of variance (Kruskal-Wallis test).

Results

Prognosis: A total of 162 consecutive patients (120 men, 42 women) met entry criteria for the study. The median age was 58 years (range 33 to 89). Fourteen patients (8.6%) died in hospital and 32 more died from cardiovascular causes in the long-term follow-up period (median 4 years, range 1 to 10).

Hospital mortality was 4% (3 of 75) among patients with less than 0.05 mV of ST-segment depression in leads V_1, V_2 and V_3 (group 1), compared with 13% (11 of 87) in patients with at least 0.05 mV of ST depression in these leads (group 2). The sum of ST-segment depression was significantly related to hospital mortality when tested with the logistic model ($p < 0.001$). The risk of hospital death was greater with increasing amounts of ST-segment depression, without any evidence for a risk threshold.

The sum of precordial ST depression in leads V_1, V_2 and V_3 was significantly correlated with the sum of inferior ST elevation in leads II, III and aVF ($R^2 = 0.30$, mean squared error 3.8, $p < 0.0001$). While the sum of inferior ST elevation was also a predictor of hospital mortality, it was a weaker predictor than the amount of precordial ST depression. The sum of inferior ST elevation did not contribute prognostic information after adjusting for the sum of precordial ST depression in a stepwise logistic model.

Multivariable logistic regression was used to determine whether the prognostic information provided by precordial ST-segment depression regarding hospital mortality was independent of other potential prognostic factors. The prognostic importance of the sum of precordial ST-segment change remained significant ($p < 0.003$) after adjusting for the effects of the patient's age, sex, number of cardiac risk factors (hypertension, diabetes, smoking, hyperlipidemia, and family history of coronary disease), history of angina pectoris, history of cerebrovascular or peripheral vascular disease, admission chest roentgenographic findings, and initial Killip class. The year of hospital admission was not correlated with hospital mortality and its inclusion in the logistic regression model did not affect the significant relation of precordial ST depression with hospital mortality. The results were unchanged when the 9 patients with minor ST elevation in V_4, V_5 or V_6 were omitted.

Precordial ST depression was also significantly correlated with the likelihood of urgent complications during the initial hospitalization. Urgent complications (as defined in Methods) occurred in 24 of the 75 patients (32%) without precordial ST depression (group 1) and in 46 of the 87 patients (53%) with precordial ST depression (group 2). The sum of precordial ST depression was significantly related to the probability of developing urgent complications ($p = 0.002$ by the logistic model). This relation remained significant ($p = 0.0097$) after adjustment for the effects of the other clinical factors of potential prognostic value noted above.

The analysis of complications was repeated after excluding the patients who died during the hospitalization. Urgent, nonfatal complications occurred in 21 of the 72 patients (29%) without precordial ST depression and in 35 of the 76 patients (46%) with precordial ST-segment depression. The sum of precordial ST depression was significantly related to the probability of developing urgent, nonfatal complications ($p = 0.026$ by the logistic model). This relation was of borderline statistical significance ($p = 0.055$) after adjustment for other prognostic factors, probably because of the smaller sample size after exclusion of hospital deaths.

Survival after hospital discharge also differed depending on the sum of precordial ST-segment depression present on the admission ECG (Fig. 1). The survival at 1 year, 3 years and 5 years, calculated by the Kaplan-Meier method, was 96%, 94% and 92%, respectively, in group 1, and 89%, 86% and 80%, respectively, in group 2. The sum of precordial ST-segment change was a prognostic factor of borderline statistical significance, when tested univariately with the Cox model ($p = 0.058$). Multivariable analyses of long-term prognosis were not performed because of the borderline significance in the univariate analyses.

Comparison of QRS changes: The patients in groups 1 and 2 were compared to examine whether precordial ST-segment change was associated with a different extent or location of infarction by means of the QRS scoring system.[12,13] QRS scores could not be calculated in 3 of the 75 patients from group 1 and 4 of the 87 patients from group 2 because of development of bundle branch block, insertion of a pacemaker or lack of follow-up electrocardiograms. The median interval between the admission and predischarge electrocardiograms was 11 days.

Groups 1 and 2 had distinctly different patterns of infarction as judged by the QRS scoring system (Table I). Patients without ST depression (group 1) had significantly fewer overall QRS points ($p = 0.041$ by Kruskal-Wallis test), suggesting that the total area of infarction was smaller. Groups 1 and 2 were no different, however, in the number of QRS points developed in leads reflecting the inferior wall. If precordial ST depression were the result of anterior ischemia, a higher frequency of associated anterior infarction would be expected. There was, however, no significant difference in the amount of anterior QRS change between the 2 groups. Supporting the hypothesis that precordial ST depression indicates posterior epicardial injury was the observation that patients in group 2 had significantly greater amounts of posterior infarction ($p = 0.0012$). The amount of apical infarction was also significantly increased ($p = 0.0086$) when ST elevation in V_4, V_5 and V_6 accompanied ST depression in leads V_1, V_2 and V_3. These differences in the distribution of QRS points was not changed appreciably by excluding the 10 patients who had reinfarction before hospital discharge.

TABLE I Location and Mean QRS Points Relative to Precordial ST-Segment Depression

Leads	Precordial ST Depression: Absent (Group 1, n = 72)	Precordial ST Depression: Present (Group 2, n = 83)	p Value
Inferior (II, aVF)	3.6	3.6	0.880
Posterior (V_1,V_2)	0.5	1.0	0.001
Anterior (V_1–V_4)	0.3	0.4	0.701
Apical (V_5–V_6)	0.4	0.8	0.009
Lateral (I, aVL)	0.0	0.1	0.506
Total	4.8	5.9	0.041

Discussion

The major finding of this study was that patients with precordial ST-segment depression during an inferior AMI have a poorer prognosis. Patients with precordial ST depression had a hospital mortality rate of 13%, compared with 4% in the remaining patients. The risk of hospital death increased directly with the sum of ST depression, without evidence for a threshold, and the prognostic information it provided was independent of that provided by clinical factors and by the amount of inferior ST elevation. Finally, precordial ST depression was also predictive of urgent complications during the hospitalization among patients who survived.

Previous studies of precordial ST depression as a predictor of hospital mortality have yielded conflicting results. In the initial study by Shah et al,[2] hospital mortality was 21% (5 of 24) in patients with precordial ST depression, compared with 0% (0 of 20) in patients without ST depression. No other study has found as high a mortality rate in patients with precordial ST depression, and none had confirmed a significant difference in hospital mortality.[3–6,8,18]

The present investigation differs from previous studies in 2 important respects. First, most reported studies have included fewer than 50 patients, and none has included more than 110 patients with inferior AMI.

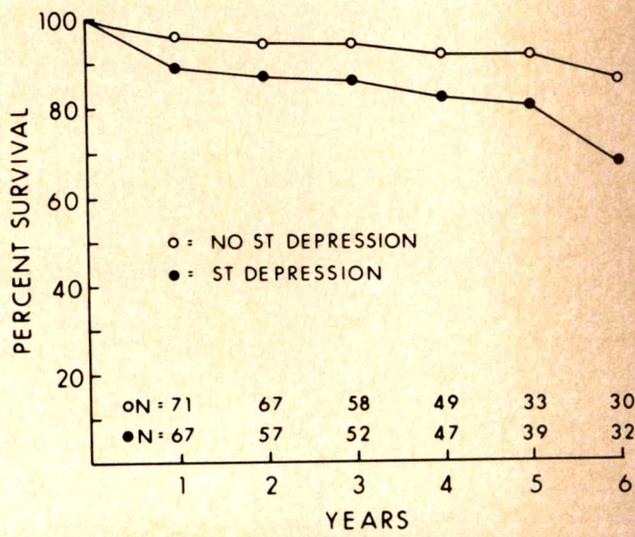

FIGURE 1. Cumulative survival of patients discharged from the hospital, according to the presence or absence of precordial ST-segment depression on the admission electrocardiogram.

The small sample sizes may have prevented previous studies from detecting real mortality differences. In most previous studies an insignificant trend toward higher hospital mortality related to precordial ST depression was present.[2,4–6,8,9,20] Second, the present study analyzed precordial ST depression as a continuous variable, rather than as simply "present" or "absent," to use all available information and increase statistical power.[14] Smaller sample sizes and insensitive statistical methods are particularly likely to mask clinically important differences in mortality.

Our results also suggest that the long-term prognosis of patients with precordial ST depression is worse than that of patients without this finding (Fig. 1). Among patients discharged from the hospital, the 5-year survival was 80% in patients with and 92% in patients without ST depression ($p = 0.058$ by Cox analysis of the entire survival curve). Previous studies have reported follow-up data after discharge from the hospital, but none has documented important differences in long-term mortality after discharge.[4–6,18,19] The largest study, that of Wasserman et al,[19] found equal mortality 3 years after inferior myocardial infarction whether or not precordial ST depression was present among 219 patients enrolled in the Aspirin Myocardial Infarction Study. However, patients in that study were highly selected and may not be representative of all patients with inferior infarction; all were Killip class I or II during hospitalization, and all had survived for at least 2 months after discharge before enrollment. The present study differs from previous studies by having more patients, or longer follow-up, or both.

Pathogenesis of ST depression: The mechanism of precordial ST depression remains controversial. ST depression might occur as a passive "reciprocal" phenomenon. We found, as others have, that the sum of ST elevation in the inferior leads II, III and aVF was correlated with the sum of precordial ST depression in leads V_1, V_2 and V_3. This correlation need not imply that precordial ST depression is a benign electrical phenomenon, however. Precordial ST depression was a stronger predictor of prognosis than inferior ST elevation, and the latter was not significant in the multivariable analysis.

Precordial ST depression may indicate a larger infarction. We examined this possibility by means of the QRS scoring system that correlates well with the location and extent of myocardial infarction.[12,13] Patients with precordial ST depression had larger total QRS scores, suggesting that they had larger infarctions (Table I). The size of the inferior infarct itself was similar, however, whether or not precordial ST change was present. Patients with ST depression in leads V_1, V_2 and V_3 had associated posterior wall and apical infarction significantly more often than patients without this ECG finding. In contrast, anterior and lateral infarctions were not associated with precordial ST depression. These observations suggest that precordial ST changes mark a group of patients with larger infarcts that often include the true posterior wall and apex.

The present study was not designed primarily to investigate the mechanism of precordial ST depression. Data from additional ECG leads, coronary angiography and ventriculography, which could have shed further light on the pathophysiologic mechanisms, were not available on most subjects. Our observations concerning the correlations between ST changes and QRS changes on the electrocardiogram are in broad accord with the findings of other investigators using more sophisticated techniques.

Most previous investigations have also found evidence of larger myocardial infarctions in patients with precordial ST depression. The peak creatine kinase level is usually higher in patients with precordial ST depression,[2–6] although this has not been a uniform finding.[17] Larger areas of inferior infarction in association with precordial ST-segment depression have also been disclosed by thallium-201 perfusion imaging.[4,6] Global left ventricular ejection fraction has usually been found to be lower in patients with precordial ST depression,[2–4,6] with 1 exception.[1] Several studies have examined regional wall motion abnormalities and correlated them with precordial ST change. These studies are difficult to compare because of variations in technique and nomenclature. Most found more extensive inferior wall motion abnormalities,[2,4,6] but disagree on the presence of other regional abnormalities. Some studies found no difference in wall motion outside the infarct zone,[1,4,6] while others found additional anteroseptal,[2] apical[3] or posterolateral[3] abnormalities.

Another potential cause of precordial ST depression is anterior ischemia due to concomitant disease of the left anterior descending coronary artery. In our study, evidence of associated anterior infarction was not more common in patients with precordial ST depression. Previous investigations disagree whether an association exists between left anterior descending disease and precordial ST depression, with some studies finding an association,[8,9] while others have not.[4,10] Scant evidence for anterior wall ischemia has been found with either thallium-201 perfusion imaging[4,6] or positron emission tomography.[20] The data are insufficient to establish anterior ischemia as the cause of most cases of precordial ST depression during inferior AMI, but cannot exclude it as a contributing factor in some cases.

Implications: Therapeutic decisions in patients during and after AMI depend on accurate assessment of prognosis, and precordial ST changes during inferior AMI may provide a valuable noninvasive method of classifying patients into high- and low-risk groups. Information from the admission electrocardiogram is available immediately, at no risk and little cost, in even the smallest community hospital. In high-risk patients, interventions aimed at reducing risk may be appropriate, while in low-risk patients, conservative therapy and rapid rehabilitation may be more suitable. Precordial ST changes mark patients at high risk of hospital complications or death, probably because of a larger area of infarction. Thrombolytic therapy is being investigated as a method of salvaging acutely jeopardized myocardium, and may be particularly indicated in patients with precordial ST depression during inferior AMI. While similar prognostic information may be

available from other methods (such as perfusion scintigraphy or radionuclide angiography), the immediate availability of such information from the admission electrocardiogram is an obvious advantage when rapid decisions must be made.

Isosorbide Dinitrate Sublingual Therapy for Inferior Myocardial Infarction: Randomized Trial to Assess Infarct Size Limitation

PEDRO PABÓN OSUNA, MD, LUIS M. GARCÍA MORENO, MD, ANTONIO ARRIBAS JIMENEZ, MD, ANGEL SALA SÁNCHEZ-CASTILLO, MD, CÁNDIDO MARTÍN LUENGO, MD, JOSÉ SÁNCHEZ HERNÁNDEZ, MD, LUIS CASTAÑO BAZO, MD, MANUEL CASCÓN BUENO, MD, MAXIMILIANO DIEGO DOMINGUEZ, MD, and CLAUDIO LEDESMA GARCÍA, MD

To assess the potential of isosorbide dinitrate sublingual therapy for limiting myocardial infarct size, 41 patients with inferior acute myocardial infarction (AMI) were studied. Twenty patients were randomly assigned to the control group and 21 to the treatment group. Patients in the treatment group received 10 mg of isosorbide dinitrate every 2 hours for 72 hours. To estimate infarct size, QRS scoring, peak creatine kinase (CK) serum levels and CK curves were used. There were no significant differences between the 2 groups in maximal or cumulative activity of CK or QRS score (percent of left ventricle infarcted: 16% in the control group, 17% in the treatment group). In both groups the QRS score increased significantly by 13 hours after AMI, and the increase was highly significant by 19 to 23 hours. Thus, sublingual isosorbide dinitrate at the dosage given did not reduce infarct size in patients with inferior AMI.

(Am J Cardiol 1985;55:330–334)

Isosorbide dinitrate, which is used for treatment of angina, has recently been used in the management of heart failure complicating acute myocardial infarction (AMI) and other heart diseases.[1–4] Isosorbide dinitrate is a vasodilator agent with a direct major effect on systemic veins and a mild but significant relaxing action on arterial smooth muscle.[2,4,5] The resultant reduction in intramyocardial tension and decrease in myocardial oxygen demand is probably the main mechanism in relieving angina and enhancing ventricular function in patients with heart failure. There is some evidence of dilating action on coronary arteries with improvement in collateral circulation and coronary blood flow in AMI.[6–8] Therefore, we undertook a prospective, randomized study to test the hypothesis that sublingual isosorbide dinitrate could significantly reduce infarct size. We selected 2 homogenous groups of patients with inferior AMI. The infarct size was estimated by analysis of changes in serum creatine kinase (CK) and by QRS scoring from standard 12-lead electrocardiograms (ECGs).

Methods

Patients and criteria for inclusion: This study initially included 49 patients admitted to the coronary care unit who were suspected of having their first AMI, located in the inferior wall. Forty-one patients met all the inclusion criteria and 8 were excluded. The inclusion criteria were (1) typical chest pain, (2) epicardial injury pattern in leads II, III and aVF and pathologic Q waves in the same leads, (3) absence of electrical signs of right or left bundle branch block, anterior fascicular block and ventricular hypertrophy, (4) systolic blood pressure on admission greater than 100 mm Hg, (5) no history or electrical signs of previous AMI, and (6) no evidence of cardiac failure on admission.

QRS scoring system: In all patients a 12-lead ECG was recorded at enrollment and 2, 4, 6, 8, 10, 12, 16, 20, 24, 30, 36, 42, 48 and 54 hours later. The QRS scoring system used was that developed by Selvester et al,[9] as modified by Wagner et

al[10] (Table I). All records were scored by 3 cardiologists independently without knowledge of the origin of the tracing. Interobserver agreement of the overall QRS score of every patient was assessed by analysis of variance. When significant differences among the 3 cardiologists were found, the QRS score mean value was taken.

Measurement of infarct size by enzymatic indexes: On admission and every 6 hours, blood samples were taken until 15 samples were collected, and the CK activity was measured in each sample. From the actual values, intermediate points (every 3 hours) were calculated by a method of curvilinear interpolation,[11] and expressed in IU/liter. The index chosen for biologic estimation of the infarct size was the cumulative activity of creatine kinase (CKr)[12]: $CKr = E(T) + Kd \int_0^t f(t)dt$, where E(T) = the actual concentration of enzyme, Kd = the constant of elimination and $\int_0^t f(t)dt$ = the area under the curve. Kd was obtained in each case from values of descending branch of the CK curve after transformation to a monoexponential regression equation.

Hemodynamic data: For 72 hours systolic and diastolic blood pressure (BP), central venous pressure and heart rate were measured every hour.

Treatment groups: On admission the patients were randomized to the control group or the treatment group. The patients admitted on Monday, Wednesday or Friday were assigned to control group and those admitted on Tuesday, Thursday or Saturday were included in treatment group. The control group included 20 patients who received no cardioactive drugs during the study. The treatment group included 21 patients, all of whom were treated with sublingual isosorbide dinitrate, 10 mg every 2 hours for 72 hours. The first dose was always 10 mg, but if at the time of administration of subsequent doses the systolic BP was less than 100 mm Hg, the dose was reduced to 5 mg. The groups were comparable with respect to QRS score of the first ECG, CK values at entry, sex distribution and age.

Statistical analysis: *QRS scoring:* the differences between the QRS scores of both groups were assessed by Kruskal-Wallis test.[13] The differences among QRS scores in each group were determined by the Friedmann test and Wilcoxon-Wilcox test, using the Pearson and Hartley tables.[14] To compare the QRS changes in both groups curves of repeated measures of the QRS score over time were constructed.

Enzymatic analysis: We studied the maximal activity of CK (CKp), time to peak of CK (Tck), CKr and Kd. A Student *t* test was applied to differences between control and treatment groups. To study the differences in Tck between both groups, a Mann-Whitney U test was applied. The analysis of correlation among enzymatic variables was assessed using a multilinear regression test.[15] To study the correlation between QRS score and enzymatic variables, a Spearmann test was used.[16]

Hemodynamic indexes: Systolic and diastolic BP, central venous pressure and heart rate were recorded. To assess the differences between the initial values of each variable and its average value over 48 hours, the Student *t* test for paired samples was used. The significance of the differences between both groups was studied by the Student *t* test for small and independent samples. In the treatment group the individual values of BP measured before every dose of isosorbide dinitrate were compared with the values 1 hour after sublingual administration of the drug; a Student *t* test for paired samples was used for analysis.

Results

QRS scoring system: In the control and treatment groups the mean evolution time between the onset of symptoms and the admission of the patients to the coronary care unit was 3 hours (range 0 to 9). On admission the mean QRS score was 3 points in both groups. The maximal values were 6.6 points in control group and 6.9 points in treatment group (difference not significant [NS]). The Kruskal-Wallis test showed no statistically significant differences in QRS score between the groups throughout the study period. Analysis of the QRS score, estimated by Wilcoxon test showed that the increase of QRS score from the first ECG was significantly different at 13 hours of evolution of AMI ($p < 0.05$) and was highly significant ($p < 0.0001$) at 19 to 23 hours. From this time the QRS score continued to increase, but very slowly, so that the trend curves showed a marked flattening. The statistical significance of the differences from the first ECG increased over the study period. Significant differences between the QRS score at 23 hours and subsequent records were not

TABLE II Enzymatic Values in Control and Treatment Groups

Parameters	Control Group	Treatment Group
CKp (IU/liter)	1,185 ± 493	1,142 ± 449*
CKr (Hr × IU/liter)	1,646 ± 676	1,734 ± 824*
Kd (hour^{-1})	0.042 ± 0.007	0.044 ± 0.001*
Tck (hours)	20 ± 5	21 ± 7*

* No significant differences between groups.
CKp = peak creatine kinase level; CKr = accumulated CK activity; Kd = enzyme disappearance rate; Tck = time to peak CK.

found. Figure 1 shows the similarity of QRS scores in both groups and the flattening of the curves at about midpoint.

Enzymatic estimation of infarct size: On admission all patients were in the upslope of their enzyme curves; the initial values of CK were 128 ± 45 and 138 ± 52 IU/liter in the control and the treatment groups, respectively. The mean values of CKp were 1,185 ± 493 IU/liter in the control group and 1,142 ± 449 IU/liter in the treatment group. The CKr mean values were 1,646 hours × IU/liter in the control group and 1,734 hours × IU/liter in the treatment group. The respective values of Kd were 0.042 and 0.044 hours^{-1}, whereas the Tck reached 20 ± 5 hours in the control group and 22 ± 4 hours in the treatment group. The differences between the mean values of each measurement in the 2 groups were not statistically significant (Table II). In the control group a good correlation between CKp and CKr ($r = 0.97$) was found, although the correlation was better ($r = 0.99$) when Tck and Kd were included. Similar results were found in the treatment group. Analysis of correlation among the 4 enzymatic variables yielded very high coefficients of determination, showing that each variable can be expressed as a function of the others by a multiregression equation.

Correlation between QRS score and enzymatic variables: The analysis of correlation between QRS score and enzyme levels yielded the following results: (1) The Spearmann test showed no correlation between peak QRS score and CKp or CKr. (2) The Tck did not show correlation with the time to peak QRS score. (3) When QRS scores were individually measured at the Tck, a slight but significant correlation was found between them and the CKp ($r = 0.48$ and 0.49 in control and treatment groups, respectively, $p < 0.05$).

Hemodynamic features (Table III): The average systolic BP at entry into the study was 125 ± 18 mm Hg in the control group and 135 ± 23 mm Hg in the treatment group (NS). The diastolic BP was 78 mm Hg in the control group and 87 mm Hg in the treatment group (NS). In both groups the average BP in the first 48 hours of evolution of the AMI was significantly lower than the value at entry. The decrease in BP in the treatment group (16%, $p < 0.0001$) was larger than that in the control group (7%, $p < 0.05$). In the treated patients the individual values of BP before every dose of isosorbide dinitrate were compared with the values 1 hour after the intake of the drug. The average systolic BP values were 125 ± 12 mm Hg before treatment and 110 ± 10 mm Hg 1 hour after sublingual administration of isosorbide dinitrate (11% decrease, $p < 0.0001$). The diastolic BP decreased from 82 ± 10 mm Hg before the intake of the drug to 75 ± 10 mm Hg 1 hour later (8.5% decrease, $p < 0.0005$). At entry into the study the mean central venous pressure was 7 mm Hg in both groups and the heart rate was 74 ± 11 and 73 ± 15 beats/min in the control and treatment groups, respectively (NS). The changes in these measurements during the evolution of AMI were not statistically significant.

TABLE III Mean (± Standard Deviation) Hemodynamic Values on Admission and During the 48 Hours of Evolution of Myocardial Infarction

Discussion

Loss of myocardial mass is the most frequent cause of pump failure and the major determinant of short- and long-term prognosis in patients with AMI.[17,18] Over the last 10 years, attempts to limit infarct size have gained a prominent place in research of therapy during AMI. Preliminary reports have shown that the intravenous nitroglycerin reduces the enzymatically estimated infarct size.[19–21] Nevertheless, it is not clear whether nitrates administered orally, sublingually or topically may be useful for this purpose. Like nitroglycerin, isosorbide dinitrate may have the potential of reducing infarct size, because it reduces the myocardial oxygen demand by a decrease in the preload and afterload. To test this hypothesis, we studied the effects of isosorbide dinitrate in patients with inferior AMI, selecting the QRS scoring system and changes in serum CK as index to estimate infarct size.

QRS scoring system: To estimate the infarct size, analysis of changes in serum CK,[12] nuclear ventriculography[22] and electrocardiographic changes[23] have been used. Selvester et al[9] reported a method based on the accumulation of points obtained from Q-wave duration and R/Q and R/S amplitude ratio on standard 12-lead ECG (QRS scoring system). Wagner et al[10] developed a simplified version of this method, testing only quantitative criteria and comprising 37 criteria with a total of 29 points. Correlation between QRS scoring and percent of infarcted left ventricle showed that 1 point of the score represents infarction of about 3.5% of left ventricle in an anterior infarct[24] and 2.5% in an inferior infarct.[25] In our study the highest QRS score achieved was 6.6 points in the control group (percent of left

ventricle infarcted = 16.5%) and 6.9 points in the treatment group (percent of infarcted left ventricle = 17%); this difference was not statistically significant. Also, the serial ECG showed a similar evolutionary trend in the 2 groups. Our results suggest, therefore, that isosorbide dinitrate did not affect the evolution of AMI during the first 54 hours of the acute coronary event. In our patients the QRS score showed a rapid increase in the first 24 hours and a very slow increase during the remainder of the follow-up period; similar increases in QRS score have been reported by Anderson et al[26] between the second and third day of the inferior infarcts. A good correlation (r = 0.74) between QRS score and anatomically estimated infarct size has been proved,[25] suggesting that changes in the QRS score are related to changes in the infarct size. Nevertheless, other mechanisms have been postulated. An increase of extravascular fluid in the infarcted myocardium, which could explain QRS changes, has been experimentally proved.[27] Hutchins and Bulkley[28] have reported the "infarct expansion" mechanism, in which the infarcted myocardial wall stretches and thins, increasing the proportion of infarcted myocardium exposed to surface electrodes. Nevertheless, neither mechanism explains the results of our trial, because both have been observed from the fourth day of the onset of infarction, and our patients were studied within the first 2 days. Therefore, in our trial, the increase in QRS score is probably related to an increase of the necrosis area. Although the causes of late extension of the infarct are not clear, Anderson et al[26] suggested that the blood flow in the border zone is reduced, small hemodynamic changes could result in an increase in the extent of the infarct. Anderson et al[26] suggested that interventions initiated later than the first few hours after the onset of symptoms may have more potential for limiting infarct size than previously considered. The results of our trial suggest that the infarction process in the left ventricle progresses the most within the first 24 hours of the AMI; after that period, progression of the infarct is very small. Because of this, attempts to limit the infarct size should be instituted within the first 24 hours after the onset of AMI.

Enzymatic estimation of the infarct size: Statistical analysis yielded no significant differences in mean enzymatic values between the control and treatment groups. The CK curves were used to assess the effects of therapy aimed at limiting infarct size. Although several studies indicated a good correlation between CKr and anatomically estimated infarct size,[29] some shortcomings of the method should be noted. Essentially, CK kinetics are based on a 2-compartment system, whereas the curves of the enzyme are based on a 1-compartment mathematical model; consequently, the Kd can be underestimated, leading to miscalculation of CKr.[30] However, the good correlation between CKp and CKr reported previously[31] and found in the present trial suggests that the CKp can be taken as an alternative in infarct size estimation. In our study, 6-hour sample intervals for CK analysis were chosen because it has been suggested that this time should encompass the CKp.[31] The reperfusion of an occluded coronary artery produces an important and fast enzymatic release, which could suggest a large infarct when in fact it is associated with small necrosis[32]; although isosorbide dinitrate is not a thrombolytic agent, the possibility of a spontaneous revascularization in some patients cannot be excluded in our study. Another factor reducing the sensitivity of the enzymatic method in inferior infarct is the association of right and left ventricular necrosis.[33] No patients of the present study showed clinical or electrical signs of right ventricular involvement. Finally, some pharmacologic interventions can disturb the fractional disappearance of CK,[34,35] although we do not know whether isosorbide dinitrate has some effect in this regard.

Correlation between QRS score and enzymatic analysis: In the present study no correlation was found between the peak QRS score and CKp or between the time to peak QRS score and Tck. However, when the QRS score was taken at the Tck, a mild but significant correlation was found. These signs suggest that there could exist a delay between QRS changes and enzymatic changes. Seino et al[36] reported good correlation between enzymatically estimated infarct size and QRS score on the seventh day after the onset of AMI, but not the third day. We suggest other explanations for the relatively low correlation between QRS score and enzyme levels. Initially, some studies showed that the pathologic Q waves can be masked by the current injury and unmasked when the current injury disappears[37,38]; we do not know whether this mechanism has had some influence on the results of our study because we have not analyzed the relation between the ST-segment resolution and QRS changes. On the other hand, if "infarct expansion" is present, the infarct estimated by QRS score can seem larger than that measured by enzyme levels. Finally, if the reperfusion of an occluded coronary artery occurs, the enzyme-estimated infarct size could seem larger than studied by QRS changes.

Hemodynamic aspects: In control and treatment groups, the average BP during the follow-up period was significantly lower than that at entry into the study, perhaps related to adrenergic tone during the acute event. Nevertheless, the decrease in BP was more prominent in the treatment group ($p < 0.0001$) than in the control group ($p < 0.05$). Additionally, in the treated patients, an average decrease of 11% in systolic BP ($p < 0.0001$) and 8.5% in diastolic BP ($p < 0.0005$) was found after every dose of isosorbide dinitrate. Similar results have been reported by others.[2,4,5] In contrast, in the control group, the BP did not change significantly during the follow-up period. Consequently, although the complete right-sided cardiac catheterization was not performed, our results provide indirect evidence for drug effects.

Acknowledgment: We thank Juan Macias, MD, Manuel Urrutia, MD, Antonio P. Urdaniz, MD, and, very especially, the nurses of coronary care unit for their help in evaluation of these data.

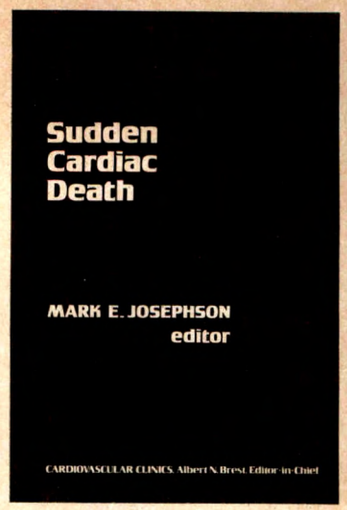
SUDDEN CARDIAC DEATH

The latest monograph in the **Cardiovascular Clinics** brings you the most up-to-date information on this topic in 20 never-before-published papers.



Sudden Cardiac Death,

Cardiovascular Clinics, Volume 15, Number 3

In this state-of-the-art report, a team of 53 recognized authorities share the latest research into topics including

- the pathology of sudden death
- initiating events
- the epidemiology of sudden death
- identification of patients at risk
- the latest trends in pharmacologic therapy
- new antiarrhythmic drugs
- preventive strategies, and
- pediatric sudden death.

This invaluable reference will better arm you to lower the toll from sudden cardiac death. Order your copy today.

Edited by **Mark E. Josephson,** MD, Robinette Foundation Professor of Medicine, University of Pennsylvania School of Medicine; Chief, Cardiovascular Section, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania; with 52 additional contributors. About 320 pp. Illustd. Ready March 1985. About $50.00.

Contents:

• The Pathology of Sudden Death. • Electrophysiology of Experimental Models of Sudden Death. • Role of the Autonomic Nervous System in Sudden Death. • Platelets and Prostaglandins in Sudden Death: Therapeutic Implications. • Initiating Events of Sudden Cardiac Death. • Epidemiology of Sudden Death: Insights from the Farmingham Study. • Clinical Characteristics of Sudden Death: Implications for Survival. • Coronary Artery Spasm: A Mechanism for Sudden Death. • Identification of Patients at Risk for Arrhythmic Death: Role of Holter ECG Recording. • Signal Averaging Methods to Select Patients at Risk for Lethal Arrhythmias. • Mechanism of Lethal Arrhythmias: Results of Programmed Electrical Stimulation. • Use of Programmed Electrical Stimulation to Predict Sudden Death after Myocardial Infarction. • Electrophysiologic Testing of Survivors of Cardiac Arrest. • Pharmacologic Therapy for Survivors of Sudden Death Based on Programmed Stimulation. • The Selection of Antiarrhythmic Regimens by Electrophysiologic Studies: Techniques and Results. • Clinical Pharmacology of Old and New Antiarrhythmic Drugs. • Beta-Adrenergic Blockers in the Prevention of Sudden Death. • The Role of Antiarrhythmic Drugs in the Prevention of Sudden Cardiac Death. • Mechanisms and Surgical Management of Ventricular Tachyarrhythmias. • Sudden Death in Infants, Children, and Adolescents.

Albert N. Brest, MD, is the Editor-in-Chief of the Cardiovascular Clinics.

Also of Interest —

Exercise and the Heart, 2nd Edition — Cardiovascular Clinics, Volume 15, Number 2

Totally new, this 2nd edition explains the latest uses of exercise in the prevention, diagnosis and treatment of heart disease. Effects of cardiovascular drugs on exercise testing and training, supervised versus nonsupervised exercise rehabilitation, exercise training of patients with ventricular dysfunction and heart failure, and exercise testing in non-coronary heart disease are among the many important areas discussed.

1. McAreavey D, Ramsey LE, Latham L, et al: "Third drug" trial: comparative study of antihypertensive agents added to treatment when blood pressure remains uncontrolled by a beta blocker plus thiazide diuretic. *Br Med J* 1984(Jan 14); 288:106-111.

Apresoline® hydrochloride

hydralazine hydrochloride USP

TABLETS

INDICATIONS

Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS

Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS

Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary.

Complete [illegible] antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms.

A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.

Use MAO inhibitors with caution in patients receiving hydralazine.

When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy

Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS

Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore be used with caution in patients with suspected coronary artery disease.

The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.

In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improve

According to a recent study appearing in the British Medical Journal[1]

The most "acceptable" antihypertensive to use with a beta blocker and a diuretic is...*

...function has been noted where control values ...e below normal prior to Apresoline administra... ...n. However, as with any antihypertensive agent, ...esoline should be used with caution in patients ...h advanced renal damage.

...ipheral neuritis, evidenced by paresthesias, ...nbness, and tingling, has been observed. Pub... ...ed evidence suggests an antipyridoxine effect ...f the addition of pyridoxine to the regimen if ...mptoms develop.

...od dyscrasias, consisting of reduction in hemo... ...bin and red cell count, leukopenia, agranulocy... ...is, and purpura, have been reported. If such ...normalities develop, discontinue therapy. Periodic ...od counts are advised during prolonged therapy.

...e Apresoline tablets (10 and 100 mg) contain ...&C Yellow No. 5 (tartrazine) which may cause ...rgic-type reactions (including bronchial asthma) ...ertain susceptible individuals. Although the over... ...ncidence of FD&C Yellow No. 5 (tartrazine) ...sitivity in the general population is low, it is ...quently seen in patients who also have aspirin ...ersensitivity.

...VERSE REACTIONS

...erse reactions with Apresoline are usually revers... ...when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.

Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.

Less frequent: Nasal congestion; flushing; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION

Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.

The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.

In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

HOW SUPPLIED

Tablets, 10 mg (pale yellow, dry-coated); bottles of 100 and 1000.

Tablets, 25 mg (deep blue, dry-coated) and 50 mg (light blue, dry-coated); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.

Tablets, 100 mg (peach, dry-coated); bottles of 100.

Dispense in tight, light-resistant container (USP).

C80-15(1/80)

Consult complete product information before prescribing.

More acceptable than Aldomet® (methyldopa) or Minipress® (prazosin HCl)†

"Hydralazine was the most generally suitable third drug...."[1]

The lowest number of side-effect complaints per patient

Aldomet® was responsible for an average of 4.1 complaints per patient, Minipress® an average of 2.8, and Apresoline an average of 1.8.[1]

These results were obtained in a recent comparative study in which Apresoline, Aldomet and Minipress were added to the regimen of 40, 36 and 43 hypertensives, respectively,[1] whose blood pressure had been inadequately controlled by a combination of a beta blocker and a thiazide diuretic.

As with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.

*In terms of patient acceptability, based on side-effect profile.
† Apresoline was found marginally superior to Minipress.

Before prescribing, please consult Brief Summary of Prescribing Information above.

Apresoline® hydralazine HCl

linical Clues to MIXED ANGINA *No. 5*

The stairs seem steeper today

Most days she can climb the stairs with no difficulty. But today she was less than half-way up when an angina attack stopped her.

That's the unpredictability of MIXED ANGINA—vasoconstriction coexisting with fixed coronary lesion, to produce a critical reduction of myocardial blood flow.

And because vasoconstriction is an unpredictable event, ischemia and pain occur unpredictably:

- at varying levels of exercise
- at rest, or even during sleep
- upon exposure to cold
- under emotional stress
- diurnally, typically in the morning

PROCARDIA® (nifedipine) is a primary therapy for the patient with MIXED ANGINA. It prevents vasoconstriction in both large coronary arteries and coronary arterioles to maintain myocardial blood flow and oxygen supply. At the same time, PROCARDIA dilates peripheral arteries to reduce afterload and myocardial oxygen demand.

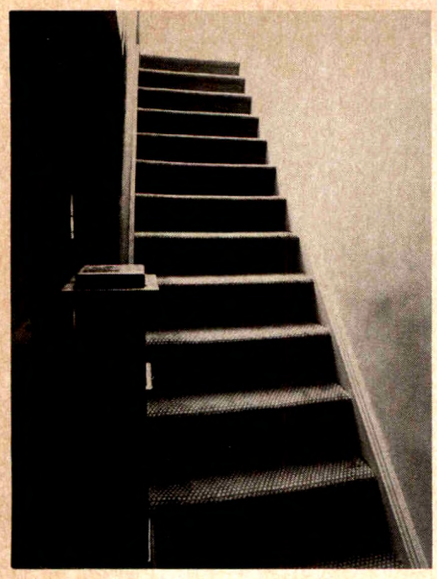
As a result, PROCARDIA can significantly reduce your patient's angina attack rate and need for nitroglycerin.[1]

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Primary Protection in
MIXED ANGINA

Please see PROCARDIA® (nifedipine) brief summary on next page.

The stairs seem steeper today



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

PRIMARY PROTECTION IN MIXED ANGINA

Usual Effective Dosage: 30 to 60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level a a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and th patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration c severity of angina on starting PROCARDIA or at the time of dosage increases.

A Favorable Safety Profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 106:644-652, 1983.

Brief Summary
PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestiv heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricula dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phos phatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA (nifedipine) therapy is uncertai in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symp toms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have bee reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregatio and increase in bleeding time in some PROCARDIA patients. No clinical significance for these findings has bee demonstrated.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 pa tients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blockin agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination ma increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlle studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteer The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with corc nary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which d goxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, an discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin ar ticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80% and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg p day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently recei ing cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two yea and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a do approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mi and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used durir pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edem nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5 palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramp nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramp flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balanc dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, pu pura, allergic hepatitis, gingival hyperplasia, and erythromelalgia. Very rarely, introduction of PROCARDIA therapy w associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of t disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardi infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular a rhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CA SULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperatu 59° to 77°F (15° to 25°C) in the manufacturer's original container.

...with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leakage. Monitors valve function over time.
- Color spectral patterns locate and grade shunts.
- Displays ECG trace for time reference. Phono trace for correlation of heart sounds with Doppler flow velocity patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Visken® (pindolol)

5-mg and 10-mg Tablets

More than 7 million patient-years of experience

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken® (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/ kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.
